Aas, Norway*

Abstract

Soil contamination caused by the addition of compounds that result in adverse effect on soil functioning is a matter of great concern. Trace metals include a great number of elements in the periodic table of elements, and their biogeochemistry and impact on living organisms can be very different. It is well known that some are essential up to a critical limit where they become toxic, and others are directly toxic even in small concentrations. Over the years, the research has focused on unraveling their sources, reactions in soils, and impact on the ecosystem. Several assessment techniques have been applied to estimate the biological risks, and some of those are discussed here. Contamination is caused by both geogenic and anthropogenic sources, which are described. The source of contamination is important to understand the biological response to environmental concentrations determined. The determination of metal concentrations includes total digestions of soils with concentrated acids under high temperature and pressure, extractions using complexing agents and weak extraction solutions, evacuation of soil solutions, and installation of devices accumulating metal ions directly from moist soils. The latter have been made possible by applying the diffusive gradients in thin films and the technique is discussed in relation to its capacity in estimating bioavailability. We present studies where the speciation of metals in soil solution has been carried out using the speciation models Windermere Humic Aqueous Model/Model VI, in combination with biological impact studies (pollution-induced community tolerance). Such combined studies provide good evidence on the fate of metal contamination in the ecosystem.

INTRODUCTION

Soil contamination is caused by the addition of compounds that result in adverse effect on soil functioning, while soil pollution is reserved to the cases where contamination is severe and leads to malfunctioning of soil function resulting in soil degradation. Soil degradation could be physical, chemical, or biological but the focus in this entry will be on chemical degradation caused by trace metals and metalloids. Chemical degradation, defined as combined negative effects of chemicals and chemical processes on those properties that regulate the life process in the soil, can be caused by natural processes or by anthropogenic activities. Trace metals with specific densities greater than 5 g/cm³, such as lead (Pb), zinc (Zn), cadmium (Cd), mercury (Hg), and chromium (Cr), are often referred to as heavy metals. Metalloids such as arsenic (As), antimony (Sb), and selenium (Se) form oxyanions and their physicochemical behavior in the environment is very different from the trace metals. Trace metals and metalloids are persistent in the environment, non-biodegradable, non-thermo-degradable and thus readily accumulate to toxic levels.

Entry of soil-borne metals and metalloids into the food chain depends on the amount and source of input, properties rate and magnitude of uptake by plants, and the extent of absorption by animals. Soil metal pollution has become a

severe problem in many parts of the world. Historically, trace metal toxicity to human health received attention because of a series of widespread poisoning. For example, the hundreds of tragic cases of human poisoning of Minamata Bay in Japan (Minamata disease) in the late 1950s were believed to have occurred from the ingestion of fish containing methyl mercuric compounds probably derived through biomethylation of mercuric salts by aquatic organisms. High concentrations of trace metals and metalloids, such as Cd, Cu, Pb, Zn, and As, in soils and crops have often been reported in a high number of countries. For example, significant adverse impacts of As-rich ground water on human health have been recorded in Bangladesh, India, and China. It is claimed that millions of people are potentially at risk from As poisoning also through food crops. Similarly, Cd accumulation in the grazing animals in New Zealand and Australia made it unsuitable for human consumption and affected access of meat products to overseas markets. There have also been concerns about urban development of horticultural sites, which contained toxic concentrations of metals and metalloids such as Cu, Pb, and As in soils resulting from excessive use of fungicides and herbicides that are rich in these elements. Following rapid social and economic development over the past several decades, soil pollution by trace metals has been both serious and widespread in China. This entry presents a brief overview of trace metal contamination, sources, their

reaction in soils, and assessment techniques to find the risk of biological impact.

Sources of Contamination

Soil can be contaminated by trace metals released from smelters, mines, waste incinerators, industrial wastewater, and from the application of sludge or municipal compost, pesticides, and fertilizers. Irrespective of their sources in the soil, accumulation of trace metals can degrade soil quality, reduce crop yield and the quality of agricultural products, and thus, negatively affect the health of human, animals, and the ecosystem.^[1]

Trace metals reach the soil environment through both pedogenic and anthropogenic processes. Most trace metals occur naturally in soil parent materials, chiefly in forms that are not readily bioavailable for plant uptake. Unlike pedogenic inputs, trace metals added through anthropogenic activities typically have a higher bioavailability.^[2] Anthropogenic activities primarily associated with industrial processes, manufacturing, the disposal of domestic and industrial waste materials, and the application of phosphorus (P) fertilizers are the major source of metal enrichment in soils.^[3] In China, sources of trace metals in urban soils and urban road dusts are mainly derived from traffic sources and industrial sources. However, the sources of trace metals in agricultural soils are mainly influenced by parent materials, mining, fertilization, pesticide application, etc.^[4]

Geogenic

Most of the trace metals occur in nature, the major source of which is weathering of soil parent materials including igneous and sedimentary rocks and coal. For example, coal is estimated to release 45,000 tons of As annually, whereas human activities release approximately 50,000 tons.^[5] Although the anthropogenic As source is increasingly becoming important, the episode of extensive As contamination of ground waters in many countries including Bangladesh, India, China, and Mexico is of geological origin. Originally transported by rivers from sedimentary rocks in the Himalayas over tens of thousands of years.^[6]

Volcanic and geological activities mobilize natural Hg from deep reservoirs in the earth to the atmosphere. Annual emission of Hg from global mercuriferous belts, the zone along plate tectonic including western North America, Central Europe, and southern China was estimated up to 500 Mg/year.^[7] In Norway, large areas of soils developed on alum shales contain substantially higher concentration especially of Cd, Cu, and nickel.^[8]

Anthropogenic

Anthropogenic activities primarily associated with industrial processes, manufacturing, and the disposal of domestic

and industrial waste materials are the major source of metal enrichment in soils. Atmospheric pollution from Pb-based petrol was a major issue in many countries where there was no constraint in the usage of leaded gasoline. While biosolids are the major source of metal inputs in Europe and North America, P fertilizers are considered the major source of trace metal input, especially Cd, in Australia and New Zealand.^[3]

Phosphate compounds contain a range of metals, which originate primarily from the phosphate rocks used for fertilizer production. Although many countries have formulated threshold levels for Cd and other trace metal accumulation in soils due to the use of sewage sludge effluents and municipal biosolids, such limits have not been established for fertilizer use. Copper (Cu) may accumulate in agricultural soils from continuous use of Cu fungicides and biosolids.

METAL BEHAVIOUR IN SOIL

Trace metals in soils are mostly partitioned in organic and inorganic fractions and not readily available to soil living organisms. However, the fraction of metals bound to solid soil fractions quickly reacting to soil physico-chemical changes is termed geochemically active. Such changes occur typically under shifts in pH and redox conditions, changes in the composition of pore water solutes like dissolved organic matter (DOM), or even changes in the quality and quantity of solid material such as iron (Fe) oxides or solid soil organic matter (SOM). The latter can take place through soil amendments of sewage sludge or different sources of Fe-bearing minerals.

The sum of geochemically active metals and the chemically labile metal fractions in pore water are often termed bioavailable (Fig. 1). The bioavailable metals can potentially be taken up by plants or other soil living organisms. The controlling mechanisms are complex as the uptake is controlled by the organism it selves, its requirements for mineral nutrients, its physiological status, uptake strategies, and internalization rates. Whether the metal uptake is controlled by diffusion or mass flow in the rhizosphere,^[9] the metal speciation in pore water and the geochemistry

Fig. 1 Schematic presentation of trace metal partitioning in soil (right side) and speciation in pore water of soils (left side).

of the different metals in the bulk soil^[10] are also the contributory factors.

The metal geochemistry depends on factors as described in a number of studies and modeling approaches.^[11–15] The most important soil factors controlling the concentrations of metals in pore water are the total concentration in soil, the concentration of solid SOM, the soil pH, and varying concentration of metal-binding solutes (ligands) in the pore water.^[15,16] The relative importance of the anionic pore water components varies, but the concentration of DOM is most important due to its high metal-binding capacity.

METHODS OF ASSESSMENT

Chemical Assessments

The total digestion of soil and sediment samples can be carried out by digesting ground material with ultrapure concentrated acid under high pressure and temperature. For direct assessment of bioavailability, the results from total digestions of soils in acid are of little value. Hence, a number of extraction protocols have been developed and implemented. Generally, these methods make use of weak acids [1.0 M ammonium (NH₄) acetate, 0.1 M hydrogen chloride, and 0.1 M NH₄ lactate], complexing agents (e.g., ethylenediaminetetraacetic acid, diethylene triamine pentaacetic acid, and trichloroacetic acid), or dilute salts (0.1 M potassium nitrate, 0.01 M calcium chloride, etc.) for the estimation of bioavailable or geochemically active metal fractions. Other more sophisticated are of methods using isotopic dilution or even sequential extraction (SE) regimes. The use of SE protocols, mostly based on the Tessier^[17] protocol, aims at describing the metal binding to different soil fractions, from water soluble through exchangeable to inert organic and inorganic soil components. The SE precision of metal partitioning between the suggested metal associations to different solid soil fractions determined with this approach has, however, been questioned.^[18,19] Despite some limitations, SE technique is widely used in pollution research and in studying the partitioning of metals in solid soil fractions.

Most functional fractionation of metals in soils seems to aim at identifying metal concentration and speciation in pore water and the concentrations being geochemically active. The remaining metal fractions are identified as geochemically inactive (Fig. 1). For the assessment of bioavailability, the use of diffusive gradients in thin film (DGT) technology has gained importance as the DGT units can be placed directly in moist soils,^[20] free water, and sediments. This provides several advantage, and the two most obvious ones are the time-integrated flux and accumulation of labile trace elements through a size discriminating gel into a resin (Chelex or Fe oxide). Second, the solid solution ratio during exposure is realistic with respect to field situations. Like uptake through plant roots, the

accumulation of trace elements in the DGT lowers the concentrations in soil solution at the surface of the device. This induces the resupply of trace elements from the geochemically active fractions in solid soil. Moreover, the DGT design restricts trace element complexes from uptake. Several studies have provided sound evidence showing unique functional applicability of the DGT technique for estimating metal bioavailability.^[21,22]

Modeling

Models capable of handling the geochemistry of soil solution require simulation of processes of solubility equilibria, including precipitation and dissolution reactions, specific adsorption on “oxide-like” surfaces, and cation exchange. The mathematical approaches to predict the free metal activity in soil solution are often done using adsorption and ion-exchange models for the various soil constituents and compare these predictions with measurements. Thus, the free metal concentration and the geochemical active metal fractions in soil can be estimated. Humic substances are recognized to play an important role in the chemical speciation of waters, sediments, and soils. Their interactions with protons and trace metals are possible to assess with an appropriate speciation code. Incorporation of humic substances into trace metal speciation models presents a major challenge due to the polydisperse nature of these materials. Humic substances are traditionally divided into three operational fractions: the soluble fulvic and humic acids and the insoluble humin. From the standpoint of speciation modeling, the two major types of metal-binding organic sites are strongly acidic carboxylic groups (ionized in the acidic pH region) and the weaker acidic phenolic groups (ionized in the higher pH region). The non-ideal competitive adsorption (NICA)-Donnan model^[13] is a combination of the Donnan-type non-specific binding of electrolyte ions in combination of the NICA model for specific binding to produce a model for metal ion binding to humic substances. The Windermere Humic Aqueous Model (WHAM) uses the site heterogeneity of DOM together with electrostatic effects and competition among protons and metal ions to describe metal binding by humic matter.^[14,23]

As the controlling variables are well known, simpler approaches are provided in the assessments of metal solubility in soil systems. These variables are, besides the total concentration of metals (M_{tot}) in soils, the soil pH, concentration of SOM, and also other metal-binding soil surfaces express as either metal oxides or clays.^[15,24,25] Sometimes these binding properties are simply expressed through the cation exchange capacity. These variables are optimized using known data on metal concentrations in pore water and hence have the tendency in being conditional to the soils used.^[12] These variables are combined into multiple regression models. Well-parameterized regression models can be applied more easily to provide at least good estimates of metal solubility in soils with

shifting concentrations of SOM or pH^[26] as long as the parameter values are within the range used for optimization.

Biological Assessments

Uptake in plants

The bioavailability of trace metals in soils has for long been connected to the uptake in agricultural crops for human and animal consumption. Cd is de facto the most studied non-essential trace metal in soil–plant ecosystem. Other metals of concern have been Hg and Pb and the metalloids As and Se. Due to the impact from trace industry on productive land and use of pesticides, the biogeochemistry of Zn and Cu has also followed closely and a large number of studies have been published. From one of our own pot studies conducted using smelter-contaminated soils, close correlation between DGT available Cd and Zn and its uptake in rye grass and spinach was reported.^[10] The speciation of Cd and Zn in soil pore water was estimated using the WHAM/Model VI.^[14] The free ion activity in pore water correlated well with the concentrations in plants, but the correlation between C_E (effective concentration) for Cd and Zn was even better. A strong linear relationship was found between C_E -Zn and the Zn concentration in ryegrass ($r^2 = 0.96$, $p < 0.001$). Since a DGT unit is unaffected by toxicity, the DGT uptake was linear with C_E only in non-toxic range of the concentration scale. The uptake stopped in spinach when the bioavailable concentrations in soils became toxic, whereas for rye grass the C_E was below toxic critical concentration. This indicates another matter of importance that the biological impact of trace metal soil contamination is species dependent.

Pollution-induced community tolerance (PICT)

Additionally, to investigating the uptake in plants and toxicity measured as reduction in growth, the development of metal tolerance in soil microbial communities has been reported.^[27,28] Microbial functions in soils are quite resilient toward metal contamination as they often recover after initial inhibition.^[29] This probably is connected to the fact that tolerant organisms replace the sensitive once, thus changing the community composition and flowingly increase its conditional metal tolerance. Almås et al.^[27] presented evidences that such metal tolerance had been developed in soil microbial communities withdrawn from the 10 different soils sampled from the same sites as investigated in the pot experiment cited above. The soils varied in physical and chemical characteristics, but the C_E and metal concentrations in pore water were determined and the correlations with acquired metal tolerance expressed as LC₅₀ [(LC50 = 50% of Lethal Concentration) 50% inhibition using the ³H thymidine incorporation method] were positive and strong. The Mtot in soils as a single parameter had no impact on LC₅₀. This showed that not only the

metal contamination but also more important the biogeochemistry of metals in soils controlled the development of PICT for Zn and Cd. Later, soil microbial communities were sequentially extracted from four soils to investigate if the strength of attachment to soil had any impact on PICT development. This was carried out by sequential dispersion and density gradient centrifugation to separate free and loosely attached cells (FLA) from strongly attached cells (SA).^[30] The results showed two remarkable findings. First, the FLA communities had developed a high metal tolerance compared to that of SA, and it was positively correlated with Cd²⁺ and Zn²⁺ in pore water ($r^2 = 0.98$ and 0.99 for FLA-IC₅₀ values against the Cd²⁺ and Zn²⁺, respectively). In contrast, SA shows no such sign of PICT. Second, the *in situ* concentration of free Cd²⁺ calculated from input parameters of pore water from field soils showed that the PICT for Cd in the test was order of magnitudes higher than Cd²⁺ in field condition. Nor the concentrations of Cd²⁺ or the total Cd in pore water in field could have affected even the most sensitive communities. The observed increase in PICT for Cd was thus not due to direct exposure of Cd. The plausible explanation for this PICT was that Zn had selected for organisms that are also Cd tolerant. These findings illustrate the importance in understanding the total biogeochemistry of metals in soils. For instance, the apparent lack in PICT development for bacterial cells identified as SA may be important when assessing the impact of metal contamination on microbial functions. Tolerant organisms may very well maintain the microbial functions, but these results indicate that investigating the biogeochemistry as a whole is of utmost importance for understanding the apparent robustness often seen in studies of microbial functions in metal contaminated soils.

Abstract

In this entry, the tropics are defined as the area with a mean summer to winter soil temperature difference of less than 6°C. With a relatively uniform temperature, subdivisions of the biome may be made on the availability of moisture. Though climate is a major determinant of the biological character of the tropics, significant differences are also introduced by the soils that are present.

INTRODUCTION

The tropics straddle the equator and by definition do not have large differences in temperature in the months corresponding to “winter or summer” of the higher latitudes. In this section, the tropics are defined as the area with a mean summer to winter soil temperature difference of less than 6°C as per the definition in Soil Taxonomy.^[1] The wide diversity of soils of the tropics is elaborated by Eswaran et al.^[2] With increases in elevation, the mean annual temperature decreases, resulting in temperature zones with corresponding differences in floristic composition. With a relatively uniform temperature, subdivisions of the biome may be made on the availability of moisture. The semiarid tropics border the deserts and occupy about 15.5% of the area, while the humid tropics include the intertropical convergence zone and occupy 11.1% of the tropical biome zone.

Within the humid area, there is a subzone where the evapotranspiration does not exceed the precipitation in any month of the year. This is, the extremely wet part of the tropics and typifies the “tropical rain forest.” In these perhumid areas, there are no dry months and annual precipitation frequently exceeds 4 m and may be as high as 12 m. Tree growth is luxuriant with several layers of vegetation. The canopy is closed, and the under-storey layers are usually very high in humidity. High humidity promotes the growth of epiphytes. Tropical rainforests provide a large amount of leaf litter, but these are rapidly humified with insignificant accumulation of organic matter in the soil. Diversity of plants is large and most of the families occur on all the continents. The humid and perhumid areas support a wide variety of animal life that clusters around specific layers of the forest. As a rule, grass-eating animals are scarce but increase where the forest grades into the savanna.

A tropical dry forest occurs in the semiarid areas. Although this is the climax vegetation, it is quickly destroyed and does not have enough resilience to regenerate. Degeneration is evident in the semiarid parts of Africa where previous forest lands lie barren after deforestation. Species diversity is also lower in the dry forests, which are generally more fragile. The dry forests give way to grasslands or savanna. In these landscapes, gallery forests where the forests follow riparian courses are frequent. In the semiarid areas, there is also considerable plant adaptation to drought conditions. Long tap roots and thick barks characterize the shrubs. The branches of the shrubs are also generally twisted and gnawed because of frequent fires. Herbivores dominate, but carnivores are also present to maintain a balance in the animal population.

Though climate is a major determinant of the biological character of the tropics, significant differences are also introduced by the soils that are present. A classical example is illustrated by areas with highly weathered Oxisols belonging to great groups such as the Acrudox and Acrustox. These soils have a very low nutrient and water-holding capacity, and consequently, even in an area with more than 5 m of rain and no dry season, the vegetation may comprise stunted trees or grass. In soils with excess water, as in some wetland areas, there is a completely different association of vegetation and animal life.

The dominant soils and the role they play in providing the character of the biomes are illustrated with a few examples. [Table 1](#) provides the area occupied by the suborders in tropical biomes.

OXISOLS

Oxisols^[3] are present in both the wet and dry tropics. Large contiguous areas of Oxisols are on the Amazon

Shield in South America and in the Congo Basin in Central Africa. Small areas occur on the volcanic islands of the Pacific and in Southeast Asia, where they form on weathering products of basic and ultrabasic rocks. On the older surfaces of Africa and South America, peneplanation has flattened the land surface. The Oxisols are generally formed on preweathered and transported sediments. One feature they have is a stone line, marking differential deposition.

The soils have low nutrient retention capacity and low water-holding capacity, and in many countries, these features have earned them the name “droughty soils.” The ability to retain anions such as phosphates, nitrates, and sulfates is high. Extremes in cation and anion retention are seen in Oxisols with a net positive charge. These properties are detrimental to plant growth, and therefore, vegetation production is very low and sometimes only adapted plants grow on these soils. The Oxisols of the high plateaus of Central Africa have a subsurface dark horizon called a sombric horizon. They are distinctive in these non-descript soils and have caught the attention of local farmers who prefer them because of their better fertility.

ULTISOLS

Occupying 7.6 million square meter (21.87% of the tropics), the Ultisols are the second most extensive soils. Although there are a few members on recent erosion surfaces, most of the Ultisols are highly weathered with few weatherable minerals and occur on stable geomorphic surfaces.^[4] The landscape is generally undulating. Ultisols occur in association with Oxisols and also share many of the physicochemical properties. Water and nutrient retention is also low, and some, as the Oxisols on old landscapes, have stone lines.

The Ultisols have an argillic or a kandic horizon, and the latter soils are generally associated with older landscapes. On the old surfaces of Central Africa and the Amazon

Shield, lithological discontinuities, sometimes with stone lines, are common in the Kandiusults and Kandiidults. Clay content differentiation in the upper part of the soil, a defining characteristic for Ultisols, is generally due to geomorphic processes: clay translocation and accumulation to form an argillic horizon, and it is a relict feature in many Ultisols or confined to the soils on younger surfaces.

Organic matter content is related to moisture saturation. Some Ultisols (humults), which occur at high elevations in cooler environments, also have high organic matter. For low-input farming, these organic matter-rich soils are frequently the first choice for food production. Ultisols are preferred to Oxisols for grain production, but the latter soils are generally highly rated for perennial crops such as rubber (*Hevea brasiliensis*).

Many Ultisols (and some Oxisols and Alfisols) have plinthite.^[5] Plinthite is a sesquioxide-rich, organic matter poor material, which has a reticulate pattern with reddish and white colors. It forms under aquic conditions, and when the water table is lowered and the surface exposed, it can harden to ironstone. Soils with plinthite are considered as degraded because their productivity is low, and they are also difficult to manage.

ALFISOLS

The Alfisols are the pedological equivalent of the Ultisols with a high pH or base saturation. They are preferred to Ultisols for their better nutrient status and easy workability. The Alfisols are more frequent in the semiarid tropics. In the humid tropics, they occur on specific rock types, such as limestone and/or basic rocks, or at locations where there is an external source of bases. The dust from the Sahara (Harmattan winds) and Kalahari deserts add large quantities of carbonates to the soils of Central Africa, and so Alfisols are extensive in Africa.

Alfisols, particularly the Ustalfs, which have a longer period of moisture deficit, are widely used for food crop production. In the wet season, they grow maize, sorghum, and soybeans. As moisture stress increases, the variety of crops grown in the absence of irrigation includes chickpeas and millet. In the Ustalfs and in some of the Udalfs, sugarcane is an important crop. In the drier tropics, the Alfisols and the other soils are used for grazing. Managed pastures are modern, and in many countries, the carrying capacity for animals is frequently exceeded. With an adequate supply of water and nutrients, particularly nitrogen (N) and phosphorous (P), these are one of the most productive soils of the tropics. The other very productive soils are the Molisols, but these are not very extensive.

INCEPTISOLS AND ENTISOLS

The alluvial soils of valleys and coastal plains have been the sites for agricultural development in Asia. These soils

are naturally wet or can be puddled for rice cultivation. The Entisols occur on the flood plains, while the better developed Inceptisols are on older surfaces. In the semiarid tropics, rice is grown during the wet season while an upland crop is attempted, if adequate moisture is available, for much of the growing period. In Africa, wet Inceptisols and Entisols were traditionally avoided because of heavy infestation with pests and diseases. The African farmer prefers to cultivate the better drained upland soils.

On the coastal plains of the tropics, acid sulfate soils occur, and they are more extensive in the tropics than in temperate areas. Being formed under brackish water conditions, they support unique vegetation and are also a unique ecosystem. These soils occur in association with the peats or Histosols. The characteristic feature of acid sulfate soils is the presence of a mineral called pyrite (FeS_2). In the Entisols (sulfaquents), the process of FeS_2 formation is active. The Entisols commonly occur close to tidal flats and are generally continuously reduced. The bearing capacity of such soils is low, and due to the presence of FeS_2 , the soils are not cultivated. Drainage of such soils, or where the soils have been naturally drained by downcutting of rivers, results in oxidation of the upper part of the soil with a concomitant ripening process. The FeS_2 oxidizes and alters to a yellow mineral called jarosite and in the process liberates sulfuric acid that lowers soil pH. This chemical transformation is considered to be the greatest acidity change in soils. The resultant soil is an Inceptisol (sulfaquept) and has the dubious status of being the most acid soil. Many sulfaquepts are used for rice production with low production and even crop failures.

Large areas of the tropics (Table 1) are covered with sandy soils (Psamments). The largest extent is in the desert margins of the Sahara and the Kalahari, in Africa. The Kalahari sands have been blown eastward into parts of Botswana, Zimbabwe, and Zambia, where they bury former Ultisols and Oxisols. Toward the north, the Kalahari sands occur in Congo as large, broad tongues. Most of the soils on these broad deposits are Psamments, but in the depressions, they are associated with Spodosols.

The upland Inceptisols and Entisols occur on steep sloping land. The soils are shallow because of continuous downwearing by water erosion. The tropical udepts and ustepts and the orthents are commonly found under shrub or forests. Land conditions prevented their cultivation, although these soils are also being used for agriculture because of scarcity of land in many of the poorer countries.

VERTISOLS

Only the Vertisols^[6,7] of the tropics have been used for agriculture in low-input systems. These soils are sticky and plastic when wet and extremely hard when dry and so cannot be managed with the traditional bullock-drawn plows. In India, e.g., when mechanical power became

available, the soils were only planted at the end of the rainy season.

Vertisols are very productive soils for agriculture.^[8] The pH is between 6 and 7.5, and the soil is well supplied with nutrients. Vertisols do not have adverse quantities of toxic elements and are not deficient in any nutrients, but they must be supplied with N and P for sustained productivity. They are derived from basic parent materials, and the largest extent is in India (on the Deccan Plateau) and bordering the Nile in Sudan.

OTHER SOILS

Mollisols, Aridisols, Histosols, Spodosols, and Andisols occur in small areas in the tropics. Mollisols are present in the cooler areas, with an isothermic soil temperature regime. Tropical Aridisols form a small band in Africa and in India. Their properties are similar to Aridisols of other biomes.

The Histosols^[9] are very extensive in Southeast Asia and mainly in Sumatra and Kalimantan of Indonesia. They are found on the coastal plains of these islands. They also occur at similar physiographic settings in the other countries. Unlike the Histosols of northern latitudes, the tropical Histosols are woody and have buried timber. Some also have acid sulfate features. These soils are extremely difficult to manage because of their very acid nature and the many nutrient (specifically, trace element) deficiencies. The beach ridges on the coast create a basin inland where the Histosols form under aerobic conditions. Associated with the Histosols are the Spodosols of the coastal platforms in the tropics. Spodosols are formed on sands and have a bleached surface E horizon with an organic matter rich subsurface horizon. A lateral seepage of organic colloid-rich water from the peat swamps into the sand result in the formation of a “spodic-like” B horizon.

The Andisols occur on the circum-Pacific belt of volcanoes. They are present in all countries of this orogenic zone. Generally, they share the properties of the temperate Andisols but have a lower content of organic matter. Some of the Andisols with udic soil moisture regimes, particularly those occurring on the older surfaces, have a net positive charge, similar to the Acrudox. The upper part of the soil may have a net negative charge as long as there is organic matter, and

so organic matter management is crucial to the productivity of these soils.

Turbations

Brad D. Lee

Department of Plant and Soil Sciences, University of Kentucky, Lexington, Kentucky, U.S.A.

Robert C. Graham

Soil and Water Sciences Program, University of California, Riverside, California, U.S.A.

Abstract

Mixing of soil material through natural mechanical action is collectively referred to as turbation. The turbations of some kind operate in most soils. Often effects are minimal but in some soils, turbations are a dominant process that strongly impacts the soil morphology and may even overwhelm the effects of other processes. Turbations can be categorized as bioturbations, cryoturbations, and pedoturbations. Bioturbation is the mixing of soil material by organisms. It can occur slowly through root growth or quickly through tree throw, burrowing invertebrates and mammals. Bioturbation by mammals and invertebrates promotes the formation of thick, organic-rich A horizons and retards the differentiation of illuvial horizons. Cryoturbation, the dominant soil process in many Gelisols, is the mixing of soil material through freeze–thaw processes. This process orients rock fragments within the soil, transports organic-rich A horizon material into the subsoil, and disrupts the lateral continuity of soil horizons. Pedoturbation is the disruption of soil horizonation by the self-mixing of soil material. This process is common in smectite-rich soils with a high shrink–swell capacity where surface material falls into large, deep cracks during dry climatic periods. The most extreme examples of this process in clay-rich soils are Vertisols. Pedoturbation also occurs in petrocalcic horizons. The precipitation of calcium carbonate within voids in these cemented horizons causes expansion and internal shattering, resulting in cracks that are sites for more calcite precipitation, and the process is continued.

INTRODUCTION

Various processes act within soils to physically disturb and mix the soil material. These natural processes are in general referred to as *turbations* and prefixes are added to more specifically categorize them as *bioturbations*, *cryoturbations*, and *pedoturbations*. The turbations of some kind operate in most soils. Often their effects are relatively minimal, and the development of soil horizons is primarily under the influence of such processes as leaching and illuviation. In some soils, turbations are a dominant process that strongly impacts the soil morphology and may even overwhelm the effects of other processes. The mechanisms responsible for the different kinds of turbations, and the resulting effects on the soils in which they operate, are explored in the following sections.

BIOTURBATION

Mixing of soil caused by organisms, either flora or fauna, is known as bioturbation. Soil is the basic rooting medium for

plants and, while root growth itself disturbs soil fabric, the process is generally so slow and localized that a mixing effect is not obvious. A much greater impact results from tree throw, i.e., the uprooting of trees, usually by wind. When a tree falls, a root wad, consisting of soil and rock enmeshed by coarse roots, is pulled out of the ground (see Fig. 1). The soil material held in the root wad is eventually eroded and released in a mixed heap on the soil surface. Forest fires speed the release process by burning the fallen tree and its roots. Where tree throw is common, relatively weakly developed soils result in a hummocky landscape.^[1] In some cases, tree throw lifts soil horizons intact and lays them back as an inverted profile rather than fully mixing them.^[2]

Animals digging in or burrowing through soil can be very effective mixing agents. The mixing power of earthworms has long been recognized.^[3] Earthworms bring organic material from the surface down into the mineral soil. As they travel through the soil, they ingest, and intimately mix, both organic and inorganic materials throughout the zone in which they are active. This generally produces a thick, dark, organic-rich A horizon (mollic or umbric epipedon) and can counteract the

Fig. 1 An example of bioturbation: Tree throw has lifted root wads of soil and rock that will eventually be deposited in a mixed mound on the soil surface.

development of illuvial horizons.^[4] Bioturbation has also been attributed to other invertebrates, including ants, termites, and crayfish.^[5]

Burrowing mammals are powerful bioturbation agents. Pocket gophers are among the most active burrowers, as they continually explore the upper several decimeters of soil for food and habitat. Other burrowers, such as prairie dogs and ground squirrels, have more fixed tunnel systems but still effectively mix the soil, often digging into underlying soft bedrock, thereby deepening the soil–bedrock boundary.^[6] Some predators, such as badgers, coyotes, and bears, pursue these small burrowing animals by attempting to excavate them, and in the process, they disrupt even larger volumes of soil. Bioturbation by mammals, as with earthworms, tends to promote the formation of thick, organic-rich A horizons and to retard the strong differentiation of illuvial horizons. Bare soil thrown out of burrows is subject to raindrop impact and erosion, but thorough mixing of the surface soil, as accomplished by gophers, may improve aeration and water infiltration.

Bioturbation by mammals can have direct impacts on environmental quality and cultural resources. Burrowing can move environmental contaminants from the surface to deeper within the soil^[7] and can break through subsurface barriers constructed to retain contaminants in landfills.^[8] Pocket gopher and other macrofauna activity in archaeological sites can destroy the stratification of artifacts, confounding interpretations.^[9]

CRYOTURBATION

The churning and mixing of soils caused by freezing and thawing is known as cryoturbation. Freezing of water in the soil causes expansion, subsequent thawing causes collapse, and together the resulting forces mix the soil in complex patterns (Fig. 2). Cryoturbation

Fig. 2 An example of cryoturbation: Freeze–thaw processes in a Gelisol have mixed organic matter into the subsoil in convoluted patterns. Scale is in centimeters.

Source: Photo provided by J.G. Bockheim.

dominates in many Gelisols, where an “active layer” overlies the permafrost. The active layer, usually <2 m thick, is frozen during the cold season but thaws in the summer and is a zone of intense cryoturbation.^[10] During freezing, liquid water migrates to freezing fronts, both near the surface and at the underlying permafrost, and the soil mass expands at those locations when the water freezes. Cryoturbation orients rock fragments within the soil, transports organic-rich A horizon material into the subsoil and upper permafrost, and disrupts the lateral continuity of soil horizons.^[11] Ice wedges in the permafrost also promote cryoturbation.^[12] When soil temperatures drop below -30°C in the winter, the already solid ice in the permafrost recrystallizes and shrinks by 3%, forming vertically oriented cracks. In the spring, water from the active layer migrates into these cracks and freezes, with a 9% increase in volume (at temperatures between 0°C and -30°C). The resulting ice wedges slowly expand over the years and generate subsoil pressures that must be resolved in an upward direction, thereby contributing to cryoturbation. The effects of cryoturbation in permafrost areas can also be seen at the soil surface in the form of patterned ground, with polygonal nets of sorted stones, frost-heave ridges, and frost boils.

Although cryoturbation is most strongly expressed in permafrost regions, it also occurs in temperate zone soils where freezing is limited to the upper part of the soil. Frost heave churns the upper several centimeters of these soils, lifting rock fragments and uprooting seedlings. The effect is pronounced where the soil is bare, not insulated by snow cover or leaf litter.

PEDOTURBATION

Some soils undergo substantial swelling when they are wetted and shrink upon drying. The resulting disruption

Fig. 3 An example of pedoturbation: Shrink–swell processes in a Vertisol have forced lighter-colored subsoil material toward the surface.

Source: Photo provided by T.D. Cook.

of the soil is called pedoturbation and is generally associated with clayey soils that are rich in smectite, the most extreme expressions of which are Vertisols. When the soil swells, often with differential wetting patterns,^[13] its fabric is sheared upward along slickensides, bringing subsoil material toward the surface (Fig. 3).^[14] When the soil dries and shrinks, cracks are formed that can be in the order of 10 cm wide at the soil surface and extend to over a meter in depth. These cracks promote mixing because surficial materials fall into them and are thus added directly to the subsoil.^[15] The morphology of Vertisols is dominated by the effects of pedoturbation, but the mixing is not necessarily so rapid that it obliterates horizons formed by leaching and illuviation, such as calcic horizons.^[16] As with bioturbation, pedoturbation in Vertisols can rapidly mix anthropogenic contaminants to some depth.^[17]

Pedoturbation is not restricted to Vertisols and other clayey soils. Minor shrink–swell behavior is present in most soils, and to some degree, it can alter the soil fabric. Narrow shrinkage cracks (<5 mm) under desert pavements allow eolian dust to infiltrate into shallow B horizons where it is incorporated into the soil fabric, slowly building the soil upward.^[18] In another example, the rock fabric of granodiorite was disrupted and converted to soil fabric by minor shrink–swell activity in the uppermost part of the weathered bedrock profile.^[19] Another type of pedoturbation happens in strongly developed petrocalcic horizons. The precipitation of calcium carbonate within voids in these cemented horizons causes expansion and internal shattering, whereupon the resulting cracks are sites for more calcite precipitation, and the process is continued. The result is a petrocalcic horizon composed of turbated and re cemented angular fragments of the original petrocalcic horizon.^[20]

CONCLUSION

Many of the mechanisms and effects of turbation on soil morphology have been explored, but the broad-scale distribution of soils impacted by tree throw and the extent of turbation effects within a soil profile have not been well documented. The mechanisms of turbation are climate dependent (macroflora and burrowing macrofauna distribution, ice wedges and freezing depth, and wetting–drying cycles). Climatic changes will impact the quantity of soils impacted by turbation, the prevalent type of turbation, and the extent to which turbation effects soil development. Pedologic investigations into the extent of turbation in varying climatic conditions are needed to predict how turbation will impact soil development in the future.

Turfgrass: Protection of Soil and Water

James A. Murphy

Department of Plant Science, Rutgers University, New Brunswick, New Jersey, U.S.A.

Stephanie L. Murphy

Soil Testing Laboratory, Rutgers University, New Brunswick, New Jersey, U.S.A.

Abstract

When man alters a landscape, changes in the soil and vegetation take place. Perennial grasses often play an important role in the structural redevelopment of the altered ecosystems. Turf is established and maintained in landscapes to enhance the environment and quality of life through stabilization and accelerated restoration of soil. Turfgrasses are frequently a part of the secondary succession on abandoned farmland and other disturbed landscapes that may take hundreds or thousands of years to restore the soil, depending on the loss or degradation of soil.

INTRODUCTION

Turfgrasses, turfs, and lawns often bring to mind connotations of a society's affluence or playgrounds of the idle rich; however, the turfed areas of many landscapes have more humble beginnings and play an important role in the protection of the earth's soil mantle. The origin of turfed areas in managed landscapes probably started along with man's effort to domesticate animals. Many centuries ago, human dwellings were close to the wilderness where predators roamed, and domesticated animals were herded and tethered close to dwellings to prevent escape and predation. Clearings eliminated cover for stalking predators, and grass provided incentive for the domesticated animals to stay put. Thus, a grazing system was developed that was necessary for survival of both man and his animals.^[1] Sheep and goats grazed the village green of ancient times, and the well-knit turf was esthetically inviting, encouraging residents to gather and socialize. These village greens became the squares or parks of many older towns and cities. Thus, this closely cropped system has become the basis for many landscapes around modern-day homes, businesses, roadways, in parks, and in other places of beauty. The total area of turfgrass in the United States has been estimated at 31 million acres, with more than 80% of the total in lawns.^[2]

FUNCTION OF TURF IN LANDSCAPES

The usefulness of closely cropped perennial grasses was probably recognized early in developing civilizations because of the important benefits in the stabilization and enhanced durability of soil under traffic. The ability to perform daily chores and recreational activities without interference from mud and dust would have been clearly recognized

by early humans. The fibrous roots of perennial grasses are recognized as the most effective means of stabilizing soil.^[3] This outstanding capacity of grasses to stabilize the soil mantle, particularly under repeated treading, enables humans to utilize the land in many ways, including parks, sports, playgrounds, and multiple other uses.^[4] The first airport runways were covered with turfgrasses until the aircraft became too large and heavy.^[5,6] Turfed runways are used for small aircraft and gliders in rural areas. The prehistoric Americans and homesteaders of the North American plains used sod to construct dwellings.^[7] Turf areas serve as recreational space for young and old. The grazed grounds around early human communities and homes probably provided for the first areas of play and sports. The game of lacrosse was modified from a sport played by Native Americans on grassed plains.^[7] Many sporting games including bowls, golf, and cricket have been played for centuries on turfgrass.^[8] Football, soccer, and baseball are the dominant sports that rely on the durability and safety of turfgrass fields. Many burial grounds are covered with turf, and many modern memorial gardens are designed into beautiful park-like settings with turf serving as the backdrop that ties together the landscape. Furthermore, a large proportion of nearly 4 million miles of public roads in the United States^[9] are bordered by low maintenance turf for reasons of safety as well as soil stabilization.

SOIL CONSERVATION

As the human population increases worldwide, the utilization of our land and soil resources continues to expand. Population growth tends to be greater in the developing countries and puts intense pressure on these societies to intensively utilize much of the available soil resources in

agricultural operations, housing, or infrastructure. Continued prosperity in developed countries fuels the expansion of suburban land development around redeveloping urban centers. These agricultural and construction activities of man result in extensive land disruption, which exposes soil to the erosive forces of wind and water. Soil erosion is a direct or contributing cause of declining soil productivity; destruction of land; sedimentation of streams, reservoirs, and storm drains; damage to roadways; mounting floods; and degradation of air and water quality.^[10] Although many individuals were conscious of the problems of soil erosion earlier, it was not until the early 1900s that the agricultural community in the United States began to regard soil conservation as fundamental to sound farming practice.^[11] Up to that time, vegetative methods of erosion control were given little attention and limited incidental use. Land development and use in urban centers have received greater attention for its impact on soil losses and the subsequent degradation of water quality, sedimentation of waterways, and severity of flooding.^[12,13]

Turfgrasses are playing an increasingly important role in enhancing our physical environment, conserving our soil and water resources, and providing recreation.^[14,15] There is considerable effort being expended to repair the landscape in China that was intentionally destroyed during the Cultural Revolution of the 1960s. Turf and trees are being replanted in China to halt and eventually reverse the severe environmental degradation of smog and dust pollution, soil erosion, water pollution, and heat buildup in cities.^[16] Turf provides a relatively inexpensive durable ground cover that protects the valuable non-renewable soil resource from water and wind erosion. Protection of soil by thick-growing vegetation takes place through several processes.^[17] One important way in which close-growing vegetation protects the land is through the interception of rainfall by the plant surfaces. This prevents the soil from the beating action of raindrops that dislodges soil particles and allows soil to move in water runoff. This positive effect can be frequently observed in runoff that is clear from turfed areas, whereas water runoff from land under cultivation or development is laden with silt, clay, organic matter, nutrients, and other materials potentially present in soil.

The maintenance of high humus or organic matter content in the soil is another benefit of keeping land in grass cover. Disruption of land is known to rapidly destroy soil organic matter. Organic matter is critical to create or maintain soil structure, the system of aggregates and pores in soil. Soils high in organic matter content typically have a rate of water infiltration that is considerably greater than that in soil low in organic matter.^[18] Greater infiltration of water into soil subsequently reduces the amount of runoff, further reducing the erosion hazard.

Another aspect of grass cover in erosion control is that it slows the movement of water over the land surface, thus reducing the erosive power of the water. Slower movement of water also provides greater time for water to infiltrate the

soil, thus reducing runoff. The dense cover of vegetation provided by turfgrass also reduces the wind velocity at the soil surface compared to bare soil and hence is effective in reducing erosion by wind; taller vegetation can reduce wind velocity to a greater degree; erosion control may depend on the extent of bare areas between plants. Grass roots are better than the roots of annual weeds and other plant species in binding soil particles together.^[3,19] These principles of reducing soil erosion—including raindrop interception, improved infiltration, slowing runoff, and binding of soil particles—in grassland systems have proven to be just as effective in turfgrass settings.^[20–23]

WATER QUALITY

Non-point source pollution is considered an important cause of decreased water quality in the United States.^[13] Soil erosion losses are a significant component of non-point source pollution. Erosion depletes land of important nutrients and organic matter content and removes the most physically suitable soil for biologic sustenance. The eroded sediment that makes its way into streams, reservoirs, and other water bodies carries nutrients such as nitrogen and phosphorus that can significantly reduce the water quality. Close-growing vegetation, including turfgrasses, plays an essential role in capturing water and filtering the sediment and nutrients in runoff.^[20,24] Turf is recommended as the vegetation to enhance environmental quality in urbanized landscapes through the stabilization of exposed soil; slowing of runoff water; promotion of infiltration; and removal of pollutants such as sediment, organic matter, nutrients, and heavy metals from runoff water.^[13,25]

SOIL ORGANIC CARBON

The loss of organic matter (carbon) from cultivated soils and other man-induced activities contributes to increased atmospheric carbon dioxide (CO₂), one of the so-called greenhouse gases.^[26] Perennial grasses are important components of ecosystems that conserve or enhance soil organic matter,^[27,28] and it is thought that a grassland system can be managed to lessen the increases in atmospheric CO₂ by a process called carbon sequestration.^[29] Perennial grass cover on soil is more effective than cover by weedy species in maintaining high soil organic matter levels.^[27]

CONCLUSION

When man alters a landscape, changes in the soil and vegetation take place. Perennial grasses often play an important role in the structural redevelopment of the altered ecosystems. Turf is established and maintained in landscapes to enhance the environment and quality of life through stabilization and accelerated restoration of soil. Turfgrasses are

frequently a part of the secondary succession on abandoned farmland and other disturbed landscapes that may take hundreds or thousands of years to restore the soil, depending on the loss or degradation of soil. Other benefits of turfgrasses to humans and the environment include temperature moderation, reduction of noise and glare, reduction of pest populations, safety via firebreaks and increased visibility zones on roadsides, airfields and security-sensitive locations, and creation of surfaces for sport and leisure activities, as well as esthetic benefits.^[15]

Ultisols

Joey N. Shaw

Agronomy and Soils, Auburn University, Auburn, Alabama, U.S.A.

Abstract

The presence of Ultisols suggests appreciable pedogenic development, although preweathered parent materials often confound this relationship. Although not extensive, these soils can be found in many parts of the world. Unfortunately, some of these soils have been abused since the 19th century and have limited genetic ability to rebound. In some parts of the world, shifting agriculture is practiced on Ultisols because amendment application is not possible. This shifting cultivation is mostly caused by limitations in soil chemical properties and not by poor physical properties or climate. If managed properly, Ultisols are capable of providing and sustaining substantial food and other resources.

INTRODUCTION

Soils classified in the Ultisol order possess a subsurface horizon (argillic or kandic horizon) with more clay than overlying horizons and low base saturation [the percentage of exchangeable calcium (Ca), magnesium (Mg), potassium (K), and sodium] in the lower portion of the soil. In some regions, Ultisols commonly possess dense, root, and water-restrictive subsurface horizons (fragipans), and hardened accumulations of iron (Fe) oxides mixed with other minerals (plinthite and ironstone). Ultisols are found in all climates except deserts. Ultisols occupy approximately 9.2% of the earth's land surface, are concentrated in tropical regions (80%), and are found in South America, Africa, China, Australia, the Pacific Islands, coastal India, and the southeastern United States^[1,2] (Fig. 1). Conceptually, the presence of Ultisols suggests: 1) in many cases, an advanced degree of soil weathering; 2) the land surface has been stable for a significant time; 3) long-term periodic wetting and drying of the soil; and 4) the soils are relatively infertile and have limited ability to replenish nutrients through inherent mechanisms. Although extensive cultivation of these soils occurs, Ultisols require that soil fertilizers and lime be added for sustainable crop production. Readers are encouraged to refer the works by West^[1], Miller^[3], Buol et al.^[4] and West et al.^[5] for detailed information.

MORPHOLOGY OF ULTISOLS

An idealized soil horizon sequence for a well-drained Ultisol consists of a darkened surface horizon (A) where soil organic matter (SOM) has accumulated; a lightened or bleached horizon (E) where materials have been removed;

a subsurface horizon (B) where clay, Fe, and aluminum (Al) oxides have concentrated; and an underlying horizon (C) that is relatively unweathered and comprised mostly of soil parent material. Transitional horizons exhibiting characteristics of both over- and underlying horizons are common.

SOM in Ultisols

Most Ultisols occur in temperate or tropical regions that possess a finite capacity to accumulate SOM due to aerobic microbial activity. Ultisols typically possess less SOM than Mollisols, Oxisols, or Vertisols, but often possess quantities comparable to Alfisols.^[1] Surface horizons (A) of poorly drained (wet) members (Aquults) as well as some Ultisols found either at high elevations or in portions of the tropics (humults) contain relatively high SOM quantities.

Horizons of Ultisols

The A and E horizons comprise the eluvial portion of the soil where leaching and erosion have removed both soluble and colloidal soil constituents. The B and corresponding transitional horizons are considered the zone of illuviation where materials have accumulated. Besides possessing higher amounts of clay than overlying horizons, most B horizons of Ultisols possess translocated clay as evidenced by clay films, coatings on ped surfaces, or clay bridges between sand grains. These subsurface horizons qualify as argillic horizons, which in combination with a low base saturation, are diagnostic of Ultisols. Kandic horizons, the other subsurface diagnostic horizon commonly found in the southeastern U.S. Ultisols, may not possess clay films.

Fig. 1 Ultisol suborder distribution.

Source: From Soil Survey Staff.^[2]

Argillic and Kandic Horizons

Argillic and kandic horizons possess more clay than the overlying eluvial horizons. Argillic horizons are thought to form through soil wetting, colloid dispersion, downward movement of clays from eluvial horizons, and truncation of movement in illuvial horizons induced by soil drying or other mechanism. Clay films are often better expressed in the lower portions of the argillic horizon because of either 1) destruction of shallow films over long periods due to eluviation or 2) mixing and destruction (bioturbation) of clay films by organisms.^[4] Because the destruction of clay films occurs in older soils, kandic horizons sometimes do not exhibit evidence of translocated clay. Although clay translocation is a formative process in Ultisol development, most soil clays likely move only short distances (few centimeters), and the majority of argillic horizon clay is derived *in situ* through mineral weathering.^[3] In addition, parent materials possessing high clay content (e.g., fine-textured fluvio-marine sediments, shales, and argillaceous limestones) contribute significant subsurface clay. Argillic horizons of well-drained Ultisols also typically possess Fe and Al oxide minerals. Argillic horizons range in color from deep red (10R hues) to yellow (5Y hues) to gray depending mostly on the quantity, type, and degree of hydration of the Fe oxides present.

C horizons of Ultisols consist mostly of parent materials that include, but are not limited to, saprolite formed from igneous and metamorphic rocks, fluvio-marine sediments, wind-blown Loess materials, local alluvium or colluvium, and thin, slightly weathered layers of sedimentary rocks (e.g., limestone, shale, or sandstone).

SOIL-FORMING FACTORS

State Factor Approach

The state factor approach proposed by Jenny^[6] surmises that soil formation is a function of climate, organisms, relief, and parent materials, acting over time. Parent materials on a local scale and climate on a regional scale, coupled with stable landscapes (function of relief), are considered the critical factors for Ultisol formation.^[3]

Parent material

Because Ultisols possess low amounts of exchangeable bases (primarily Ca, Mg, and K) by definition, parent materials low in both bases and weatherable minerals can induce their development;^[1] e.g., Gamble and Daniels^[7] suggested the weathered status of fluvio-marine parent materials of

the North Carolina Coastal Plain mandates that Ultisols be the dominant order of that region. However, Ultisols also commonly develop on parent materials high in bases and weatherable minerals.^[4] In this situation, humid environments with seasonal surpluses of moisture enhance mineral weathering and base leaching. Therefore, seasonal drying and wetting of soils facilitate argillic horizon formation, base leaching, and subsequently Ultisol development.^[3,5]

SOIL CHEMICAL PROPERTIES

Base Saturation in Ultisols

The low base criterion required for Ultisol placement (< 35% base saturation in the lower portion of the solum by the pH 8.2 sum of cations method^[2]) was originally designed to separate soils with argillic horizons that could sustain prolonged cultivation without amendment addition (Alfisols) and soils that require nutrient additions (Ultisols).^[8] In reality, the base saturation criteria are largely for classification purposes, and the genetic and fertility significance of this value is unknown.^[4] Typically, base saturation decreases with depth in Ultisols, whereas it increases with depth in Alfisols (Fig. 2). Conceptually, base recycling by vegetation is thought to control base distribution within Ultisols, whereas base recycling coupled with mineral weathering is thought to sustain bases in Alfisols. The base saturation criteria have consistently separated soils formed in acid, felsic terrains (Ultisols), from soils derived from ultramafic parent materials (primarily Alfisols) in the southeastern U.S. Piedmont.^[4]

Table 1 Response of crop yields to lime application for selecting Ultisols.

Soil	Crop	Yield (kg/ha)	
		Unlimed	Limed
Typic Paleudults	Seed-cotton ^[10]	990	1920
Typic Hapludults	Seed-cotton ^[10]	2430	2800
Typic Paleudults	Corn-grain ^[11]	2970	3920
Typic Hapludults	Corn-grain ^[11]	4700	5100
Typic Paleudults	Soybean-grain ^[12]	750	2030
Typic Hapludults	Soybean-grain ^[12]	1210	2550
Typic Paleudults	Wheat-grain ^[9]	1140	1610
Typic Hapludults	Wheat-grain ^[9]	1710	3020

Typic Paleudult is from the Coastal Plain Province of Alabama; Typic Hapludult is from the Appalachian Plateau Province of Alabama.
Source: Adapted from Adams.^[9]

Soil Acidity

Ultisols are typically acidic (pH between 4.5 and 5.5) and possess relatively high exchangeable Al. In acid soils, the synergistic effects of Al, hydrogen, and manganese toxicity, coupled with Ca, Mg, and molybdenum deficiency, result in reduced root growth and a concomitant yield decrease.^[9] Therefore, increased yields upon lime application are common for Ultisols (Table 1). This is in part caused by the amelioration of Al toxicity because of the precipitation of Al forms at pH > 5.5.

COMMON MINERALS

Low-Activity Minerals

Kaolinite, hydroxy-interlayered minerals, and Fe and Al oxyhydroxides are commonly found in the clay fraction of Ultisols. Sand and silt fractions are often dominated by quartz, with lesser quantities of mica, feldspars, ferromagnesian, and other weatherable minerals. This results in soils with a relatively limited capacity (compared to most other orders) to 1) sorb positively (+) charged nutrients [termed cation exchange capacity (CEC)]; and 2) supply bases through mineral weathering. Similarly, kandic horizons are defined by having higher clay than eluvial horizons and an extremely low CEC. Conversely, Ultisols with high Fe and Al oxide contents are capable of retaining negatively (–) charged species such as phosphate. The adsorption of phosphate on Fe oxides occurs both as a specific attraction and as a ligand exchange governed mainly by pH.

Smectites in Ultisols

Although Ultisols with low-activity clays are the most typical, areas of Ultisols containing appreciable smectite

with relatively high CEC have been found in the southeastern U.S. Coastal Plain.^[13] In this situation, the smectite is inherited from the parent material.

SOIL MANAGEMENT AND USE

Cultivation of Ultisols

The southeastern U.S. Piedmont is an example of an anthropogenically degraded soil resource. The majority of this region was in intensive cotton cultivation subsequent to European settlement. Sandy loam-textured surface horizons with appreciable SOM blanketed the region. However, monoculture cultivation and poor erosion control resulted in the destruction of these surface horizons and a degradation in this region's ability to produce row crops viably. Subsequently, this region is predominantly in pulpwood production. Forest harvesting of Ultisols can also result in nutrient losses. Buol et al.^[4] speculate that deforestation has accelerated the conversion of forest lands to savannas on Ultisols in the tropics because of the excessive removal of nutrients during timber harvesting.

Extensive acreage of cotton, corn, soybean, and peanuts in the Coastal Plain region of the United States illustrates the productivity potential of Ultisols. Cultivation of Ultisols is facilitated in this region by relatively long growing seasons, sufficient available moisture, good access to soil amendments, and favorable soil physical characteristics. Agronomic management systems that utilize reduced tillage, cover crops, and residue management that ultimately increase SOM can help sustain the productivity of cultivated Ultisols.^[5,14]

Use of Ultisols

Well-drained Ultisols that are not on steep slopes or shallow to bedrock provide few limitations for many urban applications. However, Ultisols can range from excessively drained to very poorly drained, depending on landscape position, climate, and soil and parent material permeability. Excessively drained sandy Ultisols that allow rapid leaching of land-applied chemicals, soils on steep slopes, poorly drained soils that possess seasonal high water tables for significant portions of the year, and soils with high quantities of shrink-swell clay provide severe limitations for many urban and agronomic applications. Soil Survey reports produced by the Natural Resource Conservation Service should be consulted for evaluating soil for a particular use.

SUBORDERS

At the suborder level (the next level of soil classification below order), Ultisols are separated by soil climate. Aquults occupy 0.8% of the land surface area, can be

found in most climates (except deserts), and possess seasonal high water tables for extended periods of the year that render suitability for most severe applications.^[2] These soils typically reside in depressions or other low lying positions. Their identification requires the interpretation of shallow-occurring soil wetness features (termed redoximorphic features). Humults possess high quantities of SOM in the upper portion of the soil, occupy 0.2% of the land surface area, and are mostly restricted to cooler, wetter environments.^[2] Humults occur either in mountainous terrains where aerobic decomposition of SOM is thought to be inhibited by temperature and moisture or in the tropics, where extensive root growth may lead to excessive SOM accumulations.^[3] Ustults are found in semiarid regions that typically possess sufficient precipitation during the growing season for dryland cultivation. Xerults are found in Mediterranean climates characterized by cool, moist winters, and dry, warm summers. It is thought that the excessive winter-time precipitation during lower evapotranspiration periods promotes leaching and subsequent Ultisol development in these climates. Udults are the most extensive Ultisol suborder (8.1%). These soils are found in humid environments, are fairly low in SOM, but possess sufficient subsoil moisture for dryland crop cultivation during most years. However, certain subsoil properties within udults (e.g., plinthite, traffic or tillage pans, and fragipans) may restrict root development as well as limit suitability for some urban uses.

CONCLUSION

The presence of Ultisols suggests appreciable pedogenic development, although preweathered parent materials often confound this relationship. Although not extensive, these soils can be found in many parts of the world. Unfortunately, some of these soils have been abused since the 19th century and have limited genetic ability to rebound. In some parts of the world, shifting agriculture is practiced on Ultisols because amendment application is not possible.^[2] This shifting cultivation is mostly caused by limitations in soil chemical properties and not by poor physical properties or climate. If managed properly, Ultisols are capable of providing and sustaining substantial food and other resources.

Abstract

Uranium (U) is a natural constituent of the rocks of the earth's crust. During weathering, it is released to soils and waters, where it is normally found in lower concentrations than in the basic rock materials. The oceans are the largest environmental sinks for weathered U. U is a toxic radionuclide and the heaviest of all naturally occurring elements. Its concentration is often increased by anthropogenic activities.

GENERAL ISSUES OF URANIUM (U)

Radionuclides are part of our natural environment. Their biological impact is mostly considered as negative, but some authors also claim a positive effect of low radiation for life processes, called "hormesis,"^[1] which may be the active principle of a couple of spas and mineral waters.^[2] Natural U is a mixture of the three isotopes ^{238}U , ^{235}U , and ^{234}U in the weight proportions 99.27%, 0.72%, and 0.006% and half lifetimes of 4.468×10^9 , 703.8×10^6 , and 244,500 years, respectively. An amount of 1 mg of natural U has an activity of 25.28 Bq [1 Becquerel (Bq) = 1 radioactive decay per second]. U species occur in the following four valences: U^{3+} (III), U^{4+} (IV), UO_2^+ (V), and UO_2^{2+} (VI). The predominant states in the environment are U(IV) and U(VI).^[3] This number of different valences is also one explanation for the potential toxicity of U in comparison to other heavy metals.^[4] With a specific mass of 18.9 g/cm^3 , U is the heaviest natural element. It occurs generally in low concentrations which may be elevated as a result of leaching from natural deposits or because of anthropogenic activities, such as mining, military operations employing ammunition with depleted uranium (DU; the fissionable ^{235}U has been extracted for nuclear fuel processing) penetrators, manufacturing and use of nuclear fuels, the

deposition of industrial and medical wastes, and the use of phosphate (P) fertilizers in agriculture.^[5–10]

HAZARDS OF U

Humans and animals can be contaminated by U through inhalation, ingestion, and skin contact. Inhalation is not as important as ingestion. Skin contact is particularly a threat for those working in the U industry. The ingestion of U occurs by drinking water and through the food chain via crop plants, animal feed, and animal products.

Mammals have a particularly high sensibility to U.^[3] Once the U is in the organism, it is transferred to the extra cellular fluids and transported with the blood to other organs. Uranyl (UO_2^{2+}) is the soluble form transported, and it forms complexes with protein and anions. U tends to accumulate in the body and has two modes of damaging the organism: either by radioactivity or by its biochemical toxicity as a heavy metal. Liver and kidneys are the predominant places of U accumulation. Radiation is of particular risk for lungs and bones. The most remarkable effect of U toxicity going along with low and medium contaminations is cancer. The dangers arising from the biochemical toxicity of U are generally considered to predominate the risks from its

radioactivity.^[11] The uptake with the natural element U cannot be avoided. The daily average U intake of humans with solid food is 2–4 µg. The total intake, however, is very much dependent on the U concentrations in the additional drinking water. Even at low concentration levels, drinking water accounts to more than 80% of the total U ingestion.^[7] This underlines the need to limit the uptake of soluble U compounds with waters for personal risk reduction.^[12] With the increased consumption of mineral waters, being advertised as the “better drinking water,” the relative importance of U as a threat to human health is increasing.^[13]

U IN SOILS AND PLANTS

In soils, the average U concentration ranges from 0.1 mg/kg to 11 mg/kg,^[14] with an average of 1.8 mg/kg. Mineral soils with a high content of clay can have U concentrations much above this average because clay minerals are prominent adsorbers of U.^[15] In terms of masses, water is the most significant vector for the transport of U (in solutions or by erosion) in the environment. The transport of U to natural waters occurs by diffusion or mass flow either dissolved or suspended.^[16] The solubility of U in soils depends on many factors such as, for instance, pH, redox potential, temperature, texture, organic and inorganic compounds, moisture, and microbial activity.^[15] U introduced into soils by anthropogenic activities is easily mobilized and transferred into the food chain.^[17] Soils with low fertility show higher transfer rates than do fertile soils (Fig. 1).

U IN FERTILIZERS

P fertilization is the main source for U contamination of agricultural soils. The Federal Agricultural Research Centre database for heavy metals in fertilizers records means for U concentrations (mg/kg U): 125 for single superphosphates, 219 for triple superphosphates, 43 for soft rock P, and 75 for compound fertilizers with P but less than 3 for manures. Thus, an average P dressing of 22 kg/ha P charges the soil with >20 g/ha U when triple superphosphate is used and <3 g/ha U when manures are used. In comparison, the maximum U uptake expected by crops is <1 g/ha U.

U IN WATERS

In the aquatic environment, U occurs in concentrations from 0.1 µg/L to 10 µg/L,^[18] mainly as uranyl carbonate complexes. In confined aquifers, U is found in the tetravalent stage [U^{4+} (IV)], but in surface waters it is found in the hexavalent state [UO_2^{2+} (VI)].^[4] Almost all tetravalent (uranous) compounds have a very low solubility and are less mobile than the hexavalent (uranyl) ones. The formation of hydrolysis products increases the solubility of U oxides by

Fig. 1 U concentrations in *Lolium perenne* (4th cut, 40 weeks after contamination) grown on top and subsoil material of a podzolic brown soil (sandy loam, Alfisol) under grass and forest cultivation with different fertility and U contamination. [1.5 kg soil per pot, contamination with finely pulverized green modification of U_3O_8 . Soil substrates: grassland topsoil, grassland subsoil, forest topsoil, forest subsoil; pH ($CaCl_2$): 5.9, 4.8, 3.5, and 3.8; total carbon (%): 1.2, 0.5, 2.0, and 0.6; total nitrogen (mg/g N): 1.0, 0.4, 1.1, and 0.4; plant available U (AAAC according to the study by Sillanpää,^[19] mg/kg U): 0.02, 0.03, 0.04, and 0.03; plant available P (calcium ammonium lactate, mg/kg P): 108, 20, 48, and 20; plant available potassium (K; calcium ammonium lactate, mg/kg K): 261, 246, and 25, 5.] U determination by ICP-QMS following microwave digestion with nitric acid. a complex between a metal and one or more ligands. The amount of hydrolysis products in solutions is directly related to the activity of UO_2^{2+} and the pH.^[15] Hydrolysis also competes with the formation of organic and inorganic complexes.^[7] At pH values below 4, the uranyl ion is complexed by fluorite; between pH values 4 and 7.5, it is complexed by P; and at higher pH values, complexation with carbonate to a carbonate–uranyl complex predominates.^[21] In the natural environment with typical pH values around 6 or below and in the presence of oxygen, humic acid, and fulvic acid, very stable complexes are formed.

U at higher concentrations in groundwater comes along with low pH, low adsorption capacity, lack of anions, and the presence of U ores. In comparison to this, surface waters usually show low concentrations of U because of precipitation and adsorption to bottom sediments especially at the presence of organic matter and under reducing conditions.^[15,22,23]

PROTECTION OF SOILS FROM U CONTAMINATION

Soils can be charged with surplus U by mining activities, by fertilizer use, and by the use of DU ammunition in military operations. In the first two cases, U is dispersed in the environment, whereas DU penetrators represent a typical hot spot situation; however, the extreme long half lifetime of the main isotope ^{238}U makes any contamination a permanent threat. Because of the only small offtake of U by crop plants ($<2\text{ g/ha}$), phyto-remediation (removal of U with harvests) is only a hypothetical option. Reasonable effects are only achieved by measures to further reduce the U transfer into the food chain. Most promising here is increasing the P concentrations in the soil because U has a strong affinity to form low soluble complexes with P in soils. However, the amount of P needed for significant effects is far higher than that usually applied for satisfying the P demand of crops.^[24] Together with the fact that U transfer generally decreases with soil fertility (Fig. 1), U contamination through military activities seems especially tragic for populations in crisis areas where soil fertility is usually poor. Taking all these facts into account, a clear favor should be given to strategies avoiding or reducing U contaminations of soils, such as the shutdown of U effluxes from mining operations, the removal of U from mineral fertilizers or an extended and more efficient use of manures, and finally the international ban of DU military ammunition.

Abstract

The loss of industrial manufacturing, migration to suburban areas, and economic and natural disasters have all led to large population reductions in many cities in the United States and Europe. After losing large proportions of their peak populations, a consequent land use change is often large-scale demolition of degraded residential and commercial infrastructure. The resulting large areas of vacant land represent significant challenges and opportunities for cities to reutilize this unique type of landscape. The soils that comprise vacant urban land can present a mixture of native soils affected by some early disturbance history (due to initial development) and imported soil fill material (as backfill for demolition excavation). Therefore, the specific condition of urban soils in vacant land, their quality, and associated suitability for redevelopment as green spaces can vary widely. The assessment of vacant lot soils is key to determining how these sites might be used to provide ecosystem services, including food production, stormwater runoff and flood control, biodiversity, recreation, and education. Such assessments also point to the specific management gaps that can help to guide productive utilization of these landscapes in cities where vacant land is extensive.

INTRODUCTION—THE CONTEXT OF VACANT URBAN LAND

The soils found in vacant urban lots are the unique pedogenic products of larger patterns in socioeconomic change. During the final quarter of the 20th century, economic globalization made it advantageous for industrial manufacturing operations to relocate to areas outside of traditional manufacturing centers in North America and Europe. The direct loss of employment opportunities in these cities led to massive population declines. Within these postindustrial or legacy cities, population loss was further facilitated by migration from urban core areas to suburban developments. These legacy cities are most dense in the northeastern and Central United States, where a number of cities have lost half or more of their peak populations (Table 1). Following a decline in population, the residential housing stock that comprised neighborhoods becomes vacant and falls into disrepair (Fig. 1). Demolition of these structures is touted as one way to discourage the spread of blight, leaving behind large areas of vacant land. Data on the area of vacant urban land in the United States are sparse, but surveys indicate that the total area of vacant land in some U.S. cities is significant (often >1000 ha per city; Table 1). Vacant urban land is not

unique to these legacy cities or demographic trends. The real estate foreclosure crisis and natural disasters, such as Hurricane Katrina, have also driven large increases in vacant infrastructure and land in other regions of the United States, namely California's central valley and New Orleans, Louisiana. Cities in a number of European regions (Germany, Northern England, and Eastern Europe) have also lost large proportions of their population due to similar trends of deindustrialization and migration to suburban areas.^[1] Globally, declining urban populations have been documented due to epidemics (sub-Saharan Africa), conflict (Middle East), and environmental disasters (Soviet Union).^[1] Our review of the literature, however, suggests that very little data have been published on the amount and extent of vacant urban land outside of the United States.

Vacant urban lands are dynamic socioecological systems. Vacant land is spatially distributed in a mixture of hot spots in blighted neighborhoods. Blighted neighborhoods are then dispersed across a cityscape according to more specific socioeconomic histories and trajectories. Urban areas with high vacancy rates are commonly associated with increases in crime and decreased the value of adjacent properties. On the other hand, vacant land is a natural resource that exists in some abundance and is often

Table 1 Change in peak population and vacant land in cities with the highest population losses in the United States.

City, State	% Change from peak to population in 2010	Number of vacant lots	Vacant land area (ha)

present in contiguous landscapes that are well suited to the classical definition of green infrastructure. Nassauer and Raskin^[3] provided a synthesis of conditions common to urban areas with high levels of vacancy: 1) occupied structures, abandoned structures, and vacant land occur together in irregular spatial patterns; 2) ecological legacies, or the lasting effects on a landscape of past events, are widespread, including soil contamination and degradation; and 3) due to risk adversity and lack of an economic underpinning, financial investment for redevelopment is unlikely.

There is widespread interest in transforming vacant land into functional green spaces capable of providing

an enhanced suite of ecosystem services (ES). ES are the recognized or measurable, beneficial outcomes that result from the multitude of abiotic and biotic interactions that constitute ecosystems. The concept of ES lies at the nexus of *provisioning* services, e.g., water volume inputs to the urban hydrologic cycle; *regulating* services, largely provided by soils, which can regulate the cycling of water as per the balance between infiltration and runoff; *supporting* services that include efficiency of water use by plant communities and nutrient cycling; and *cultural* services, where soils and their interaction with water resources can provide a multitude of recreational and aesthetic opportunities. Urban agriculture, stormwater infiltration landscapes, and neighborhood parks have all been identified as potential end points for vacant land conversion to green space, with each capable of enhancing ES in the core areas of legacy cities. However, the development of vacant land as green spaces must address the assessment and management of soil to realize the ecological potential of these sites.^[4] Land use history results in both high spatial variability and lasting impacts (ecological legacies) on soil conditions in urban areas. Thus, understanding the soil conditions at the site level can accelerate the success of site selection and management for green space projects in vacant urban land. This entry focuses on vacant lot soils as the product of the circumstances leading up to landscapes shifting to vacant urban land; their possible limitations and opportunities for management; and ultimately, their potential to yield ES. We will concentrate on insights provided by the assessment work on vacant urban land from the north-central and eastern United States.

DIFFERENTIATION OF URBAN AND RURAL SOILS

The properties of urban soils are affected by the type and extent of development. Although urban soils can include soils constituted for parks and sports fields (e.g., golf courses), we focus on the disturbed soils that are affected by the product of development (and demolition) in cities. These urban soils are generally considered anthropogenic soils or soils modified by human activity. The anthropogenic influence often results in the incorporation of artifact materials (building materials, wastes, etc.) into the soil profile.^[5] Historical land use and the associated disturbances are an overarching factor that influences the morphology and distribution of anthropogenic urban soil types. Long-term effects of anthropogenic disturbance commonly observed in urban soils include removal of topsoil layers, surface compaction, discontinuous soil profiles, buried soils, and physical and chemical properties altered by the presence of large quantities of debris materials. Land cover and parent material have also been found

Fig. 1 Vacant houses (A) and a vacant house being demolished (B) in Youngstown, Ohio.

Source: Photos (A) and (B) from Youngstown Neighborhood Development Corporation.

to explain variation in soil properties in urban areas.^[6] Overall, urban soils are patterned by development and demolition, whereas their rural soil counterparts are affected by agroecosystem management or degree of cover by native vegetation. Rural or predevelopment soil conditions are often used as a qualitative reference condition relating the degree to which urbanization has affected soil taxonomy, physical and chemical characteristics, and hydrology.

The construction and demolition of buildings and infrastructure are key historical disturbances that influence the properties and management of soils in vacant urban land. Residential demolitions impact soil conditions across entire residential lots, and due to the reach of heavy equipment employed in demolitions, beyond the area formerly covered by the building.^[7] The negative effects of demolition on soils may persist for many years in unmanaged vacant lots. A survey of vacant land in Cleveland, Ohio, suggested that the management potential of some sites was limited by the presence of large amounts of debris and high levels of soil compaction that were often the result of demolitions that occurred >20 years prior to the study.^[8] Alternately, vacant lot soils that have been under long-term perennial vegetation have demonstrated favorable chemical and biological properties.^[9]

MANAGING VACANT URBAN LAND FOR IMPROVED ECOSYSTEM SERVICES

The selection and addition of soil or fill materials and the removal of debris following construction and demolition, including building foundations and basements, are key management activities that affect the potential for ES on vacant land. Covering vacant land with asphalt or other impervious surfaces following demolition is among the worst outcomes for ES, as it prevents water infiltration and plant growth in the covered area. The persistence of unremoved foundations and basements in vacant lots also results in impervious areas in both soil surface and subsurface layers in the former housing area. In Cleveland, Ohio, many sites have been filled with material that is either coarse sands or fine, silty clay loam lacustrine material, neither of which retains water or nutrients well, so any attempt at intentional plantings suffers. Using a structured, sandy loam soil as postdemolition fill material in vacant urban lots, however, provides the potential for the site to support water infiltration, water retention, and plant growth. The grading of the fill materials is another key stage in the restoration process. Beniston et al.^[10] observed extremely high compaction and low microbial activity in the soil surface (0–10 cm) layer immediately after vacant houses were demolished. Heavy compaction, as well as material that is not well packed, is a somewhat common condition following demolition in vacant land. Ideally, the site should be compacted to achieve a bulk

density in the range suitable for plant growth (approximately 0.9–1.4 Mg m⁻³, depending on soil texture).

Vacant lots offer pervious surface area for infiltration and redistribution of soil moisture. The processes that mediate between infiltration and runoff regulate the potential for a vacant lot to be used as a passive, infiltrative sink for excess urban runoff volume. The role of vacant lots in the urban hydrologic cycle may offer value to local governance and utilities that can ill-afford the additional runoff volume generated by vacant areas and underutilized streets as inputs to overburdened centralized wastewater infrastructure. The potential for reuse of vacant lots as stormwater volume management is tied to the imprinting of anthropogenic disturbance as the primary soil-forming factor of vacant lot soils. When these areas were developed, the regular grid of housing or other development utilized gutters and downspouts to move runoff from impervious area (roofs) to the street and the centralized sewer collection system. The small amount of pervious area (yards) were usually sloped toward the street to encourage drainage to the street. These landforms often persist past the demolition, so that even if the soils were permeable, any runoff that did form would be routed to the street and to the centralized collection system. Shuster et al.^[7] found that soil physical and hydrologic characteristics were influenced by different levels of disturbance, namely lower (parcel area with remnant, undisturbed soils), higher (fill areas on vacant lots within the footprint of the structure), and demolition technique (burying debris on-site vs. removing debris); and in some cases, both factors influenced vacant lot hydrology. Factors that can affect the formation of runoff from a vacant lot include the proportion of vegetative cover, the absence of which can allow raindrop impact and splash erosion (sealing of the soil surface) and lower the resistance to overland flow. The sealing of the soil surface can decrease or prevent infiltration, increasing the proportion of rainfall converted to runoff volume. Apart from establishing vegetative cover on infiltrative soils, the grade of a vacant lot should be level or in the shape of shallow bowl to encourage infiltration.

Vacant land also supports urban biodiversity and directly influences the biodiversity-driven ES of pollination and pest control by providing habitat for both pollinator species and species that act as predators of herbivorous pest insects.^[11,12] A key component to realizing these ES is vegetation management, as pollinator and beneficial predator insect species benefit from increased plant diversity, increased structural diversity of vegetation, and diverse phenology of flowering species that spans the growing season.^[12] Studies of the public perception of vacant land, however, consistently report that neighboring residents prefer green spaces where vegetation is regularly maintained, as opposed to unmanaged ecological succession, on vacant urban lots.^[11] Research has also demonstrated that biodiversity

of insect and arthropod species can be maintained in highly managed urban green spaces. In a study comparing predatory insect diversity between unmanaged vacant urban lots and community gardens, Gardiner et al. reported that conversion to gardens reduced the abundance of only a few predator groups, while unmanaged lots and gardens contained similar levels of flowering plant diversity and insect diversity.^[13] Similar patterns in belowground biodiversity have been reported. A study of nematode food webs and soil properties found that the initial conversion of unmanaged vacant lots to urban gardens impacted the structure of nematode food webs, while older gardens contained food webs similar to those in unmanaged lots.^[9] That study also reported that overall soil quality was higher in gardens than in the unmanaged lots.^[9] In general, soil management practices that increase organic matter and improve soil structure ultimately support increased biodiversity by improving habitat for both aboveground plant species and belowground microbes and invertebrates.

Contamination is a key issue of concern in soils of vacant urban land. Lead (Pb) contamination is commonly observed in urban soils, with urban areas accumulating and concentrating Pb and other heavy metals (e.g., zinc and copper) during the 20th century. Sources included exhaust particulates from automobiles burning leaded gasoline, brake linings, air deposition from co-located industry, and leaded paints commonly used prior to 1978 for all manner of construction and maintenance. The U.S. Environmental Protection Agency has set a screening level of 400 mg kg⁻¹ Pb for soils in residential areas, and soils exceeding that level require further testing and additional management considerations. A survey of more than 60 vacant lots in Cleveland, Ohio, reported a wide range in the concentration of soil Pb, and many sites exceeded 400 mg kg⁻¹,^[14] though the bioavailability of Pb compounds remains an open question in need of a comprehensive assessment.

Urban soils may also be contaminated by persistent organic compounds that pose significant human health risks, including by incomplete combustion processes and are associated with traffic, any type of burning or polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs).^[15] PAHs are produced by incineration, domestic heating, and heavy industry. PCBs are industrial compounds that are no longer produced commercially, but have been deposited in the environment through widespread historical use of a variety of industrial and automotive products. Soil is a major reservoir of persistent organic compounds, and concentrations of both of these compound groups tend to be the highest in soils near sources, including highway corridors and industrial manufacturing areas.

Direct ingestion of soil and inhalation of soil born dust particles are key exposure pathways for both heavy metals and persistent organic compounds in urban soils, so establishing vegetative or mulch cover on vacant land is a key

management practice for limiting exposure. Due to the large range of variability in site history, and therefore soil physical and chemical characteristics, soil testing for fertility and selected contaminants (depending on the intended use of soils) is recommended prior to planning green space projects on vacant urban land. Soil tests for Pb are increasingly available in more locations at a reasonable cost, while testing for persistent organic compounds remains highly specialized and expensive.

URBAN AGRICULTURE ON VACANT LAND

Urban agriculture has emerged as a popular method of utilizing vacant urban land.^[16] Creating and maintaining gardens and urban farms on vacant land have the potential to provide many benefits to the surrounding communities, including fresh fruits and vegetables, improved soil quality and ES, unique educational opportunities, and the potential for supplemental income. Urban gardens can produce vegetable crop yields similar to rural sites,^[10,16] and high levels of soil quality have been observed at intensively managed urban farms. Participation in urban agriculture has been linked directly with improved diets. In cities with large areas of vacant land, it may be possible to implement urban agriculture at a scale that is capable of impacting the city's food system and food security (Fig. 2). The studies in Cleveland, Ohio, and Detroit, Michigan, estimated that a significant percentage of the fruits and vegetables consumed by the populations within these cities could be produced by using a sizable proportion of their existing vacant land for urban agriculture (Table 2).^[17,18]

Site assessment and selection are key steps in establishing urban gardens. Sites that have undergone heavy disturbances, such as demolitions, are likely to have degraded soils and require more intensive management to be productive. Soil contamination, as described earlier, is a concern, and all sites should be tested for soil heavy metal concentrations. Soil nutrient content and soil organic carbon (SOC) content are strong predictors of crop growth in urban soils, and soil testing can inform management to improve agronomic conditions.^[10,19] The selection of crops, application of amendments, adjustment of soil pH, and other aspects of site management should be based on heavy metal and nutrient test results.

In situations where vacant lot soils have been physically degraded by demolition or by other disturbances, intensive management is required to improve soil quality for crop production and improved ES.^[16] A unique soil management opportunity exists in cities, where the materials necessary to create amendments occur in great abundance and the land areas requiring intervention are relatively small. Thus, large applications of amendments such as compost and mulch can be made to soils in vacant land during the installation phase of urban agriculture or green spaces

Fig. 2 A 0.80-ha urban farm established on formerly vacant land in Cleveland, Ohio.

(Fig. 3). These applications are both capable of producing immediate impacts on soil properties and unfeasible for the larger land areas of rural farms where available quantities of materials and their cost are prohibitive. Beniston et al.^[10] reported that significant improvements to soil quality and

crop growth resulted immediately from a large (equivalent to 150 Mg ha⁻¹) application of compost produced from yard wastes to a heavily compacted urban soil. Compost application to urban soils also results in long-term increases in SOC at amended sites.^[20] SOC is a key indicator of soil quality, and increases in SOC can result in measurable enhancement of many ES. The production of compost from urban yard wastes and its use as a soil amendment for green space projects in vacant land provide multiple benefits by removing material from the waste stream and improving soils.

Cover cropping is another management strategy capable of improving the ecological function of soils in vacant land. In Youngstown, Ohio, intensive cover cropping that utilized both warm season and cool season grasses produced large amounts of biomass and resulted in measurable improvements to soil structure in a compacted urban soil.^[10] Cover crops, particularly those grown during the cooler months in northern climates, are also very effective at retaining and cycling nutrients. One caveat regarding the large compost applications described earlier is that repeated, large applications of

Table 2 Potential for crop production from urban agriculture to meet consumption demands through cultivation of vacant land in two cities in the United States.

City	Land area required	Food Production Potential	References
Cleveland, Ohio	1240 ha	22–48% fresh produce 25% Poultry 100% Honey	[18]
Detroit, Michigan	406 ha (current consumption) 1364 ha (recommended consumption)	31% Vegetables 17% Fruit	[17]

Fig. 3 An urban agriculture experiment on contiguous vacant lots in Youngstown, Ohio. The garden was established immediately following the demolition of houses in spring 2011, and the soil was heavily compacted following the demolition (A). A large quantity of compost produced from yard waste was applied to the site, and crops are growing well 6 weeks later (B).

Source: From Beniston, Lal, et al.^[10] ©2014.

compost can lead to soil nutrient levels that are in excess of crop demand. Excessive soil phosphorus (P) levels from compost application can increase the risk of water pollution from urban agriculture. This is a legitimate concern in vacant land of the United States, as urban stormwater drainage systems provide rapid transfer of runoff to surface waters. Further, many cities with large vacant land areas are in close proximity to the Great Lakes and other freshwater resources.^[3] Again, soil testing can be valuable to urban site managers to prevent excessive nutrient application via compost, fertilizer, or other amendments. Sites with excessive P levels can utilize cover cropping to retain nutrients on-site and improve soil quality, while no longer importing nutrients.

CONCLUSION

Through assessments of the soils in vacant land in postindustrial cities, we report that these landforms can provide a base of natural resources in urban areas. The soils that underlay vacant lots can present as a broad range of mixtures among soil materials and demolition debris. The variation in soil properties that results from these materials and their land use histories regulates their suitability for green infrastructure. These same assessments also illuminate the management gap and suggest ways in which demolitions might be better executed to yield vacant lots that could be used for agriculture, stormwater management, or other green spaces (Table 3). Soil testing (for chemical attributes) can be used in conjunction with soil physical and

Table 3 Best management practices for soils of vacant urban land.

During the demolition process

- Removal of building materials/debris, including basement structures
- Use of debris free, structured soil as fill material
- Grading of site to level or gently concave slope
- Minimize compaction during grading
- Apply organic matter, such as compost, to the soil surface following grading
- Establish vegetation

Site assessment for greenspaces and urban agriculture

- Conduct initial soil testing for nutrients, heavy metals, and organic matter
- Develop and implement management plan to improve soil constraints
- Continue regular soil testing

Urban Lands: and Construction Sites

Wolfgang Burghardt

Soil Technology, University of Essen, Essen, Germany

Abstract

Land use will inevitably change soil properties. Disturbance of soils and the new substrates added to soils change the morphology of the soil profile and the processes in soil. Urban soils have, therefore, different quality characteristics than natural soils. In the urban ecosystem, a new soil landscape develops, but still, this was not the subject of serious study.

INTRODUCTION

Cities in North and Latin America, Europe, and Asia are the home of more than 80% of the world's population. The demands placed on soils and therefore the targets for soil rehabilitation in urban areas must recognize the high degree of intervention by humans and the benefits of soils to the urban population and its economy.

To varying degrees (20–100%), the urban soils are covered by buildings, pavements and road surfaces, and communications and utility lines. Periodically, new free spaces will be created and rehabilitated, while others will disappear by conversion to another use. Thus, urban soils can change radically over time and acquire new properties.

URBAN SOILS

Types of Substrates

In the city, few soils retain their natural state. Other soils are young and not yet differentiated into horizons by the processes of soil development. Their properties are dominated by the characteristics of substrate of the soil. The majority of urban soils can be grouped into four ways^[1] according to the anthropogenesis of the substrates involved:

Soils modified by treatment or environmental exposure and use

The results will be of compaction; stratification; mixing; reshaping of structure; enrichment by organic substances, such as sand, gasoline, oil, and tar; contamination by toxic amounts of hazardous compounds, such as pathogenic microorganisms; acidification or alkalization; breaking of material; and sorting and separating of substrate components.

Mode of deposition of soil substrates

The methods of deposition include the following: pouring of material (e.g., rail berth); methods of tipping materials (e.g., from shovel, wheel barrows, conveyor belt, or trucks); leveling by heavy machinery; lagoon deposits; spills (e.g., harbor sludge and fly ash); blast furnace sludge; casting waste (e.g., slag), dilapidation, and demolition (e.g., of buildings); the deposition of rubble from war raids; sealing (underground and surface cover); and thorough mixing following repeated excavation and tipping.

Technogenic substrates

The technogenic substrates are from man-made material such as rubble, ashes and cinder, slag, foundry waste, industrial residues and waste, town refuse, sewage sludge, industrial sludge and dust, road paving materials, mine waste, and material from soil remediation (e.g., biological, thermal, and extractive treatment).^[2,3]

Reduction of fine earth material by increase in skeletal soil fractions

Fine earth is often mixed with building material and other technogenic substrates that are coarse-sized. Hence, the mass of fine earth in the soil volume is reduced, as is its influence on the soil characteristics.

Degradation

Most of the changes in urban soils involve a decrease in the capability of soils to fulfill the functions for the welfare of humans. The quality of urban soil can be defined by the degree to which it offers: protection against the occurrence and transfer to humans of hazardous compounds; improvement of the urban green space, climate, groundwater renewal, and concentration of chemicals; decay and safe storage of waste; and satisfactory features

for economic and social purposes. The soil characteristics required to achieve these functions are very diverse and in part contradictory.

In the urban environment, soil degradation arises from a diverse array of processes. Soil degradation can occur by enrichment with compounds from emissions of households, industry, waste tips, traffic, and maintenance work. Amendment of vegetable gardens with ash, sludge, and slag contributes to this too. Small service enterprises such as petrol stations, dry cleaners, car washes, garages, and diverse workshops are also sources of pollutants. Leakage and accidental spills from tanks, pipelines, gas pipes, sewage canals, and road tankers pollute the soils too. Fires can release harmful compounds to soils. Latrines not connected to the urban sewage canal system and the manure of dogs and other animals cause chemical soil degradation by eutrophication.

Soil degradation can be from the lack or imbalance of nutrients in plants of many urban substrates, which often results in the deficits of phosphorus, nitrogen, and micronutrients. The atmospheric deposition of protons results in acidification. Similar effects arise from tipping of acid or acid producing substrates, e.g., of high sulfide content. Alkaline dust and substrates will raise the pH. Salinity can occur from uncontrolled irrigation in dry regions or use of de-icing salts in cold parts of the world.

Physical impacts are from an increase in coarse particles (stone and gravel), which will reduce fine earth volume. Most of the man-made substrates are wastes or construction materials, which contain high amounts of coarse materials. Large areas of the city are degraded by sealing. In addition, unsealed ground is often strongly compacted. The compaction is not only confined to the topsoil as in rural sites. It also penetrates considerable depth. Soil structure can be destroyed by dispersing agents and may inhibit wetting. Decline of soil structure can result in water and wind erosion and landsliding.

The loss of humus-containing topsoil horizons and of subsoil by excavation in cities is one of the largest forms of soil loss. Excavation is the anthropogenic form of erosion.

Degradation can also mean a strong spatial heterogeneity of soil features, or the destruction and splitting of water catchment areas.

REHABILITATION OF URBAN SOILS

Hazardous Compounds

The rehabilitation of polluted urban soils has, besides others, the goal to avoid the transfer of hazardous compounds from soils to humans. The uptake of harmful compounds can result from the direct consumption of polluted soil by dermal uptake through contact of the skin with soil; oral uptake by the ingestion of dirty vegetables and fruits, drinking muddy water or direct

ingestion of soil from dirty hands; pulmonary uptake by the inhalation of fine dust from the fraction finer than 0.010 mm in diameter (PM10); and uptake through open wounds to the skin.

The primary vehicle for the uptake of hazardous compounds will be food and drinking water and the release of volatile gases and vapor from polluted soils.

The most sensitive segment of the population is children. Direct soil uptake by children occurs in playgrounds, school yards, and sports grounds. All bare soil and sand pits should contain less than the limits for compounds dangerous to children. Therefore, polluted soil and soil infected by pathogenic microorganisms^[4] must be replaced. The depth of the new soil layer should be at least 35 cm, greater than the depth to which children will dig.^[5-7] Between the topsoil and the subsoil, a geotextile could be placed to avoid deeper digging.

Earthen road materials are common in many suburban areas. They are sources of fine dust (PM10), which can be inhaled. This will be a large problem in arid and semiarid areas. Rehabilitation requires the stabilization of the road surface by binding agents or covering it by a fine gravel layer.

Polluted vegetable gardens are a source of contaminated food. There are several rehabilitation strategies practiced. The polluted soil can be replaced by clean soil. In case of heavy metal pollution, the mobility of metals can be reduced by liming. The pH values above 5.0 for most metals and 6 for cadmium and nickel will minimize the amount of plant uptake. For vegetable gardens, the uptake of pollutants can also be diminished by reducing the cultivation area of vegetables in a garden or by the growth of vegetables, which accumulate low amounts of the hazardous compounds in the plant parts consumed by humans. A possible, but rarely practiced, strategy will be the addition of compounds to soils apart from lime, which decrease the plant availability of heavy metals. Iron minerals can have such an effect.^[8] Another novel, but inadequately tested, strategy would be phytoremediation by the growth of crops that accumulate hazardous compounds and decrease the mobile fraction of the pollutant in the soil. Pollutant uptake by subsequent crops will be lowered.^[9]

Urban sites, which are degraded by the release of gases from aromatic polyhydrocarbons and mercury vapor, are generally rehabilitated by the removal of the polluted soil and its replacement by an unpolluted substrate.

From atmospheric deposition, soils of most areas of cities will be slightly polluted. Acute toxicity may not be the problem for the soils per se, but it might be of importance for long-term residents who gradually accumulate pollutants to harmful levels. Possibly, the most effective rehabilitation measures for the whole city will be a dense vegetation cover that stabilizes the soil, prevents wind and water erosion of the soil, and minimizes direct contact by humans with the pollutants.

Greenery and Street Trees

The quality of life in the cities will be enhanced by the greenery, which consists mainly of city forest, parks, lawns, and street trees. The rehabilitation of green areas can be achieved by optimizing the pH either by liming or by adding sulfur. The nutrient content can be improved by fertilizing and manuring with compost. Restrictions to the root soil volume or to aeration and available water content can be corrected by soil amelioration before planting.

Street trees live under extreme conditions, and the soil in which they grow will often be degraded.^[10] Street tree patches are often too small for aeration and water uptake. Sizes of at least $2 \times 2 \text{ m}^2$ are recommended for each street tree. When soils of street tree patches are stony or of man-made substrates of low soil quality, they can be replaced by suitable materials. For reducing the compaction and improvement of aeration, the soil around the tree can be loosened by devices that release compressed air from lances pushed into the soil. Aeration will be also improved by inserting perforated drainage pipes near the tree into the rooting zone.

Salinity

Salinity problems occur in two major forms in cities. In cold climates, streets are kept free from ice and snow by spreading salts. De-icing salts often contaminate street tree patches. The increases in sodicity may damage the soil structure of loam, clay, and organic soils. Rehabilitation measures are liming and gypsum addition, loosening or replacing loam, clay, and organic soil by sandy soil.

Soils of cities located in arid areas will often be irrigated. From groundwater and perched water near the soil surface, evapotranspiration will be increased. In arid areas, an accumulation of salts dissolved in the irrigation water will result. The secondary salinity by irrigation has to be reclaimed by loosening dense soil layers, destroying water percolation barriers caused by stone layers under fine textured horizons, and controlling groundwater depth by drainage.

In arid and semiarid areas, gypsum- and carbonate-containing soils are common. Gypsum and carbonates can form compacted layers. Excess irrigation will dissolve gypsum and also carbonates creating voids. Voids are prone to collapse and may damage the stability of buildings and streets. When irrigation water is given in small doses, and only the topsoil is wetted, the consequences can be minimized or avoided.

Sealing

A serious problem of urbanization is the sealing of soils, which limits water infiltration and green area. To a degree,

rehabilitation can be effected by changing the paved surface from impermeable to permeable materials, e.g., from tarmac to paving stone or lawn stone.

Much of the city landscape is sealed by buildings. Soil rehabilitation by unsealing is not possible. But above the sealed area, a soil layer can be established. Examples are soil covers on roofs for rooftop plantings^[11] or dense arrangements of potted plants on sealed surfaces.

Compaction

Compaction reduces water infiltration and water storage capacity of soils that are important land characteristics in cities for determining the volumes of drainage water as well as the groundwater levels and the prevalence of floods in rivers flowing through cities. It determines also the storage capacity for storm water and influences the occurrence of surface water ponding. Topsoil compaction can be ameliorated by loosening the soil before establishing the vegetation cover. On vegetated sites, deep rooting plants and liming to improve the soil structure and to favor the growth of earthworms are effective measures for improving soil porosity. However, deep compaction can only be rehabilitated by deep excavation and refilling the substrate again without compacting it.

Aeration

A significant function of soils in cities is as burial grounds. For the decay of the corpse, the soil must be well aerated. Therefore, soils from silt and clay, of very high organic matter content (>8%) and compacted soils, have generally low suitability as burial grounds.

To achieve good aeration, the soil must also be free of groundwater and stagnant water approximately to a depth of 2.5 m; alternatively, burial grounds may need drainage or a raised surface by infilling.

REHABILITATION OF CONSTRUCTION SITES

The rehabilitation of construction sites begins with demolishing buildings and ends with cleaning and improving the ground for a new use. The rehabilitation of these sites will reverse the sealing of soils.

One principle of rehabilitation of construction sites is to leave as much of the material as possible at the site. This will minimize transport cost and will not damage other sites by transferring the problems of the rehabilitation site.

Construction materials will, however, need to be inspected to separate clean materials from those that are contaminated. The different kinds of the material will also be separated for the purpose of recycling. What is not sold can be crushed to sizes that can be reused at the site either for construction, filling material, or as a substrate for

revegetation. The soil substrate will therefore often be stony, dry, calcareous, and poor in nutrients.

The management of contamination at construction sites requires documentation on individual layers of the profile and mapping of their spatial distribution. Contamination will occur in patches of variable size depending on the characteristics of the layers. The layers can be of materials that already have a certain content of pollutants (e.g., ashes, cinder, rubble, dust, and slag from nonferrous metals), or they may have a high capacity for reducing solubility or for sorption (e.g., well-buffered near-neutral pH, high carbonate, organic matter, and iron content^[12]) or high pore volume^[13] for the storage of compounds. Another significant property is the gravel content that reduces the amount of fine earth. Compounds moving through the reduced amount of fine earth will be concentrated and will increase their content in the fine earth mass.^[12]

The amount of contaminated material, which must be either cleaned or treated for immobilization of the pollutants^[14] or removed to a waste tip, should be minimized. This will be achieved by a substrate survey^[2] and excavating the individual substrate layers very carefully. For example, at a textile plant at Nordhorn, Germany, 69% of the excavated soil was separated as unpolluted or only slightly polluted.^[15] For a 65-ha area of a marshalling yard near Ruhr, Germany, the amount of aromatic polyhydrocarbon contaminated substrate was determined to be less than 10% of the total amount of the excavated substrate of the site.^[16]

Mixing of the material of different layers raises the risk of uncontrolled distribution of hazardous compounds and the creation of future unforeseen hazards. Therefore, mixing contaminated materials must be strictly avoided.

Excess material, especially if treated for immobilization of pollutants, may be heaped to create a green area at the rehabilitated site. Necessary security constructions and control measures to prevent any release of residual pollutants can be established at the heap.

For recreation areas on only slightly polluted soil substrate or of substrates with low potential for a vigorous vegetation cover, a 0.5–1 m covering of soil is usually sufficient. The soil cover should be applied without soil compaction. Therefore, the use of heavy machinery should be avoided. Alternatively, green area planning can use the different kinds of substrates for the establishment of varied vegetation types on rocky regions, raw soils (soils at an early stage of pedogenesis), acid- or carbonate-containing soils, and soils of low and high nutrient content, dry, wet, and peaty patches.

For substrates that are highly polluted, to minimize the diffusion of hazardous compounds surface or subsoil sealing is required. The soils under the impermeable sealed layer will not be exposed to leaching by precipitation. This will only work when the groundwater is well below the sealed layer.

The rehabilitation of soils polluted by organic compounds may use the potential of soils for natural attenuation due to the *in situ* degradation by microorganisms. This will probably only work for soils freshly contaminated and with low to medium contamination levels. For soils contaminated many years earlier, it can be assumed that the easily degraded compounds are already decomposed. An open question is whether the access of microorganisms to the residual polluted soil particles can be improved by *in situ* treatment. This would be an asset for the remediation of waste tips, slightly polluted soils under a soil cover and the more intensively polluted soil under sealed layers.

Urban Lands: Management

Klaus Lorenz

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

The importance of urban soils and their ecosystem services for the well-being of mankind are increasing as the global urban population is growing. Specifically, urban soils support nutrient cycling, primary and especially food production, carbon storage and regulation, water storage, pollution attenuation, and regulation of biodiversity. However, awareness for those ecosystem services must be raised among stakeholders to support urban land use planning and management for enhancing the resilience of urban ecosystems.

INTRODUCTION

Earth's urban population is growing, and thus, more people depend on the management of ecosystem services arising from urban soil functions. Among the supporting services of urban soils is primary production, i.e., the support of plant growth, in particular, in urban forests, gardens, and parks. Urban green spaces contribute to climate and air quality regulation by moderating the urban heat island and trapping airborne particulate matter. Vegetation growing on pervious urban soils promotes infiltration of water and, thus, reduces the risk of surface runoff and flooding. Vegetated urban soil supports also biodiversity maintenance. Further, many opportunities for recreation in urban areas depend on green spaces. Urban soils fulfill also many specific functions such as carrying gray infrastructure (e.g., buildings and roads) and supporting waste management. How the functions and ecosystems services of urban soils can be maintained and enhanced for the well-being of the urban population to meet their increasing demands is a major challenge for urban ecosystem management. Urban soil properties are strongly affected by demolition and construction activities, and this provides an opportunity for urban soil management toward enhancing urban ecosystem services. In this entry, soil functions and ecosystem services are presented, and it will be discussed how urban soils can be managed to enhance 1) soil carbon (C) storage; and 2) food production by urban agriculture.

URBAN SOIL FUNCTIONS AND ECOSYSTEM SERVICES

Soil is among the living foundations for the human civilization as it serves essential human needs such as those for healthy and nutritious food, freshwater, and waste absorption.^[1] Urban soils, in particular, perform critical soil functions that must be considered to support urban development.^[2] Soil functions can be distinguished with

regard to their significance in urban environments.^[3] Soil functions occur in spite of the land use as, e.g., rainwater must be dispersed or regulated, and landscaping plant roots must have air available for growth. The ecosystem services provided by urban soils are the result of inherent and manageable soil properties.^[4] Urban soil ecosystem services can be distinguished based on the Millennium Ecosystem Assessment typology. Supporting ecosystem services of urban soils (e.g., nutrient cycling and primary production) are regarded less important compared to those of non-urban soils.^[5] However, increased consumption of food produced by urban agriculture may substantially enhance primary production and associated nutrient cycling in urban soils. The importance of urban soils for the provisioning ecosystem services of food production and C storage/regulation are increasing, though, to a lower extent than those of non-urban soils. Also, flood regulation by urban soils is regarded as being of low importance on a regional scale but with a large potential for enhancement for local water storage, reduction in surface runoff, and flood control.^[5] Other regulating ecosystem services of urban soils are pollution attenuation and regulation of biodiversity.^[4] Important cultural services of vegetated urban green space which rely on soils for their biogeochemical cycling include recreation/tourism and cultural heritage. Urban soils fulfill also a range of carrying functions not addressed by the Millennium Ecosystem Assessment such as carrying structures and piped utilities.^[5]

MANAGING URBAN SOIL ECOSYSTEM SERVICES

Urban soils are used by humans for specific purposes such as green spaces, housing, and other infrastructure.^[6] Within short distances of one another, urban soils deliver very different functions and provide very different ecosystem services compared to the soil natural capital. By best planning and management practices, ecosystem service

provision by urban soils can be optimized.^[7] Soil C plays a key role for supporting, regulating, provisioning, and cultural services of urban soils. Thus, how C storage of urban soils can be managed for optimizing ecosystem services and how food production on urban soils can be enhanced will be discussed in the following sections.

Managing Urban Soil C Stock for Enhancing the Provision of Ecosystem Services

Urban land use alters soil C comprised of soil inorganic carbon (SIC) and soil organic carbon (SOC). The urban soil C stock contributes to the provisioning ecosystem service C store/regulation and the regulating service climate/temperature.^[5] Climate change can be mitigated, in particular, by storing some C derived from atmospheric carbon dioxide (CO₂) in urban soils for millennia. This long-term storage occurs as bicarbonate and carbonate ionic forms as well as carbonated salts in the solid phase. Those are among the predominant stable forms of SIC.^[8] C dating of pedogenic carbonates indicates long C residence times of >30,000 years.^[9] Similarly, radiocarbon ages of 1000–>10,000 years have been reported for SOC, especially in subsoil layers, and SOC turnover times increase with an increase in soil depth.^[10] The long-lasting legacy of urban investment decisions, growth of urban activities that produce CO₂ emissions, and increasing concentration of urban population drives urgency for urban climate change policy^[11] and for soil C-friendly urban soil and land use management.^[12] However, the recommendations listed below for enhancing urban soil C stocks should be regarded as preliminary as technologies for increasing urban soil C stocks are less well known compared to those for non-urban soils.^[13]

SIC

The urban SIC stock contributes to the provision of C storage/regulation and climate/temperature regulation. The SIC comprises both primary carbonates inherited from the parent material or deposited as dusts and secondary carbonates that form by precipitation of carbonate ions derived from root, microbial and faunal respiration, and calcium (Ca) and magnesium (Mg) ions from weathering or brought from outside the urban land unit.^[14] Carbonate-bearing soil parent materials commonly occur in urban soils.^[15] Further, demolition waste (particularly cement and concrete) may also contribute to urban SIC storage.^[16] Especially, the coarse fraction (>2 mm) of urban soils may substantially contain SIC in the form of demolition waste, limestone, and chalk fragments.^[17]

The urban SIC stock can be maintained by protecting existing stocks from losses and can be enhanced by increasing stocks (Table 1). Protection includes practices to 1) reduce soil erosion losses, in particular, during construction activities when urban soil is left uncovered. Further, SIC losses from urban areas can be reduced when 2) both excavated carbonate-containing soil and coarse fraction fragments are used *in situ* for landfilling and landscaping activities within the same urban area. Special attention should be given to urban soils heavily affected by enhanced demolition activities following military conflicts (e.g., World War II) and economic decline (e.g., Rust Belt cities in the United States) as those soils may contain high amounts of SIC as a product of carbonation of deposited concrete-/cement-derived material. Also, urban soils of arid and semiarid regions should be carefully managed for SIC maintenance as they may naturally contain high SIC stocks.

Table 1 Management practices for enhancing urban soil carbon, soil inorganic carbon, and soil organic carbon stocks.

	Protecting stocks	Enhancing stocks
Soil carbon stocks	Minimizing losses by decomposition, mineralization, and erosion during construction activities Using excavated urban soil <i>in situ</i> for landfilling and soil construction	Addition of organic material
Soil inorganic carbon stocks		Cultivating vegetation species producing Ca ²⁺ - and Mg ²⁺ -rich litter Addition of Ca ²⁺ - and/or Mg ²⁺ -containing soil amendments and waste materials Irrigation with alkaline water
Soil organic carbon stocks		Establishing vegetation on bare soil Optimizing net primary production and especially root production Urban forestry Burial of organic matter and black carbon in soil under impervious surfaces and at deeper soil depths under pervious surfaces Cultivating plant species that divert root carbon into stable mineral-associated soil organic carbon fractions

The CO₂-enriched water in the pore space may precipitate Ca²⁺ and Mg²⁺ released during decomposition of organic matter (OM) aside reacting with soil-derived Ca²⁺ and Mg²⁺. Increasing SOC stock may also amplify carbonate weathering and precipitation by promoting microbial activity which in turn causes an increase in the release of CO₂, Ca²⁺, and Mg²⁺.^[18] Thus, urban SIC stocks may also be enhanced by 3) increasing the SOC stock by adding OM or 4) by increasing urban vegetation cover producing large amounts of Ca²⁺- and Mg²⁺-rich litter. The formation of new soil carbonates requires outside Ca²⁺ and/or Mg²⁺ sources such as fertilizers, liming material (i.e., containing calcite or dolomite), or other soil amendments.^[19] Thus, 5) amending urban soils with those materials may cause an increase in SIC stocks. Other common sources and processes for carbonate occurrence in urban soils are precipitation from CO₂-enriched natural surface or irrigation water containing Ca²⁺ and/or Mg²⁺ and precipitation in soils from groundwater that has moved through carbonate-containing soils or sediments.^[20] Thus, 6) irrigating urban soils with alkaline water may result in an increase in SIC stocks as was observed, e.g., in urban soils of China.^[21,22] Waste materials in urban soils derived from construction materials may contain Ca silicate and Mg silicate minerals. Naturally, those minerals occur in basic igneous rocks including those quarried for aggregate.^[23] Those minerals are also produced in cement and iron-making and steel-making slag. Weathering of such materials (i.e., Ca-rich minerals such as silicates, hydroxides, and sulfates) in urban soils may be subsequently followed by pedogenic carbonate precipitation. Materials include Ca-rich components such as artificial mortars, plaster, concrete, natural basic rock aggregates, and slag.^[9] Thus, another recommendation to enhance SIC stocks in urban soils is 7) to use Ca- and Mg-rich materials as soil amendments.

SOC

Aside contributing to climate change mitigation, protection and increasing urban SOC stocks may also support critically important soil-derived ecosystem services, including the supporting service nutrient cycling; the provision of food, freshwater, wood, and fiber; and the regulating ecosystem services of flood control and attenuation of water quantity.^[5] The benefits of SOC are well known and related to its fundamental role for the function and fertility of terrestrial ecosystems.^[24] Specifically, there are strong interactions between SOC and soil, water, and air quality.^[25]

Urban soil management may be directed toward maintaining or enhancing SOC stocks (Table 1). The persistence of SOC is largely due to complex interactions between SOC and its environment, such as the interdependence of compound chemistry, reactive mineral surfaces, climate, water availability, soil acidity, soil redox state, and the presence of potential degraders in the immediate micro-environment.^[26] By altering those factors, urban soil

management may be optimized for SOC persistence. In urban ecosystems, SOC-enhancing management practices may be used to restore SOC in bare soils by 1) revegetation and in vegetated green space soils by 2) fertilization, irrigation, reduced soil disturbance, and residue management (i.e., returning grass clippings). Further, urban soils can potentially be optimized for SOC accumulation by 3) adding organic amendments such as biosolids, yard, and food waste during soil construction activities.^[27] In particular, lawn SOC stocks may benefit from practices targeted specifically at SOC as urban lawns are often intensively managed. Also, garden management practices, such as the addition of peat, composts, and mulches, and cultivation of trees and shrubs contribute to greater SOC stocks in urban gardens.^[28] Specifically, 4) tree planting and management of existing tree cover by urban forestry practices likely provide the greatest scope for enhancing urban SOC stocks.^[23] Urban sites covered by trees are often relatively undisturbed compared to other vegetated urban sites allowing long time for SOC accumulation. However, how to increase C restitution from tree biomass to SOC storage in urban soils is less well known.^[29]

Urban soils have often an impervious cover under which soil microbial activities are reduced, and thus, buried OM and SOC may decompose slower than those of pervious urban soils. Thus, 5) burial of large amounts of OM during the construction of imperviously covered urban soil may be a practice to enhance the provisioning ecosystem service C store/regulation. The SOC stock can be further strengthened by 6) adding “recalcitrant” compounds such as combustion derived black carbon (BC) as those may dominate SOC of imperviously covered soils.^[30] Adding BC compounds such as biochar or char to urban soils has the potential to enhance SOC stocks and improve urban soil quality.^[31–33] Further, asphalt, coal, coal ash, and tar can contribute to urban soil BC.^[34–36] However, research into the use of BC and, especially, biochar to enhance SOC and improve soil quality is in its early stages.^[37] Little thought has been given, in particular, to biochar application to urban soils and gardens.^[23]

Open urban soils should be vegetated and the vegetation maintained to optimize net primary production as this process is the primary source of soil C inputs such as plant litter and exudates and dissolved organic carbon.^[10] Best management practices (e.g., reduced physical disturbance, fertilization, and irrigation) should, in particular, 7) optimize root growth and root turnover as SOC may be primarily originating from root-derived C inputs.^[38] Further, 8) burial of soil and/or carbonaceous materials at deeper soil depths can contribute to the persistence of the provisioning ecosystem service C store/regulation.^[39] For example, enrichment of urban soil profiles mainly with anthropogenic OM up to 1.9 m depth was reported for some soils in Stuttgart, Germany.^[35] Additional storage of SOC at deeper soil depths in urban areas may also be possible by 9) cultivating plants with deep and prolific root systems.^[40] The strategy

for enhancing SOC is to select plant species that better divert root-derived C into stable mineral-associated SOC fractions. Thus, selection of appropriate vegetation in planning and design of new urban developments may be important for enhancing SOC stocks. Further, 10) adding clay-sized soil fractions to urban soils may provide preferential spots for SOC accumulation.^[41] In summary, vegetation species, soil compaction, and sward/litter management must be controlled for optimum SOC accumulation in open urban soils.^[23]

Enhancing the Provision of Food by Management of Urban Soils for Agricultural Production

Urban soils support only the provision of a small proportion of global food production as a result of urban agricultural practices. This proportion may increase as urban agriculture has been proposed as a solution for producing food in places where population density is highest, reducing transportation costs, connecting people directly to food systems, and using urban areas and their soils more efficiently. However, this expansion would require one-third of the total global urban area alone to meet the global vegetable consumption of urban dwellers, and those estimates didn't even consider how much urban area may actually be suitable and available for urban agriculture.^[42] Further, there is only a limited potential contribution of urban agriculture to global cereal production as the global annual harvested area for cereals is about 10 times greater than the global urban area. Nevertheless, urban agriculture is an important reality for many households, especially in the developing countries.^[43]

Agricultural production in urban ecosystems is challenging as urban soils are often less fertile than

non-urban soils and their biological, chemical, and physical properties are degraded. Specifically, urban soils are often compacted, low in soil organic matter (SOM), high in inorganic and organic contaminants, and characterized by altered soil moisture characteristics. As discussed previously, SOM in urban soils can be enriched for enhancing agricultural production by applying composts made from biosolids, yard, and food wastes and amending soils with BC compounds such as biochar (Table 2). Further, cover cropping and reduced tillage are intensive management strategies to increase SOM contents for urban agricultural production.^[44] Adding OM and intensive cover cropping with deep-rooted cover crops or crops having an extensive root profile are also appropriate management strategies to reduce soil compaction and improve urban soil quality. Similar to the alleviation of compaction in agricultural soils, subsoiling or deep tillage practices may be used to reduce compaction in soils for urban agricultural. In cases where it is not economically feasible to reduce soil compaction (e.g., by removing impervious surfaces such as asphalt), soils may be created on top of the compacted layers. For example, large quantities of compost, wood chips, and other forms of OM are used to create raised beds over compacted urban soil layers. However, knowledge about urban agricultural practices using raised beds is scanty.^[44]

The moisture characteristics of urban soils are altered by physical disturbance; removal or desurfacing; burial or coverage of soil by fill material or impervious surfaces; and soil, water, and vegetation management practices (e.g., fertilization, irrigation, mowing, and drainage).^[45] For poorly drained urban soils, both surface and subsurface drainage are management options to improve the soil moisture characteristics for urban agriculture.^[46] On the

Table 2 Enhancing agricultural production by managing urban soils.

Strategy	Expected outcome
Applying composts, biosolids, mulches, yard, and food wastes; adding black carbon compounds (including biochar); cover cropping; reduced tillage	Enrichment of soil organic matter; improvement infiltration and water-holding capacity
Applying organic matter, planting deep-rooted cover crops or crops with extensive root profiles, subsoiling, deep tillage, and raised beds	Reduction in soil compaction, improvement in soil quality
Surface and subsurface drainage	Improvements in soil moisture characteristics
Excavation and soil washing, bioremediation, or thermal treatment	Ex situ decontamination
Applying liming compounds or organic matter	Soil stabilization of cadmium, nickel, zinc, copper, lead, chromium, and organic pollutants
Applying fertilizers and improving soil conditions for rapid growth of microorganisms	Bioremediation of organic pollutants by microorganisms
Growing and harvesting of hyperaccumulator plant species	Phytoextraction of cadmium, nickel, and zinc
Planting trees with extensive and deep root systems	Phytodegradation of organic pollutants by microorganisms
Importing clean soil and establishing raised beds	Safe production of vegetables
Natural attenuation	Reduced concentrations of organic pollutants

other hand, urban soils may also exhibit elevated water deficit for plant growth. The previously discussed soil addition of OM in the form of compost, mulch, and other amendments can both improve infiltration and increase the water-holding capacity of soils for urban agricultural use.

Urban soils for agricultural use may be contaminated with heavy metals and organic pollutants, e.g., petroleum hydrocarbons, polycyclic aromatic hydrocarbons and polychlorinated biphenyls.^[47] Possible contamination sources are urban dust deposition and anthropogenic deposits, e.g., in derelict land previously used for industrial purposes (brownfields). Further, anthropogenic activities such as fertilization and application of sewage sludge, wastewater, and pesticides may also contribute to contamination of urban soils and restrict their use for agriculture. For decontamination, urban soils may be excavated and treated *ex situ* by using technical devices for soil washing, bioremediation, and thermal treatment (Table 2).^[48] However, more cost-effective are *in situ* methods involving stabilizing approaches for contaminants. For example, applying liming compounds or OM is recommended remediation techniques for stabilizing cadmium (Cd), nickel (Ni), zinc (Zn), copper, lead, chromium, and some organic pollutants in soils. Organic pollutants soluble to some degree in water can be treated *in situ* by bioremediation which depends on the activity of soil microorganisms. Phytoextraction that describes the uptake of contaminants by plant roots and subsequent plant harvest may also be used to reduce the concentration of Cd, Ni, and Zn in soils for subsequent urban agricultural use.^[49] Phytodegradation leading to microbial metabolism in the plant rhizosphere and subsequent degradation of organic pollutants may also be used for decontamination of urban soils. For example, poplar trees (*Populus* spp.) are hardy against many soil contaminants and growing conditions and enhance the microbial degradation of hydrocarbons.^[50] Further, organic pollutants may be removed by phytovolatilization leading to gaseous losses of organic contaminants after metabolism in plant tissues.^[49] If budgets are limited, but sufficient time is available to clean up a soil before it is used for urban agriculture, natural attenuation can be used to reduce the concentration of organic pollutants *in situ*.^[48] However, if urban soils cannot be decontaminated to levels for safe production of vegetables, establishing urban agriculture on imported clean soil or raised beds on top of the contaminated soil may be an option. As deposition of contaminants with urban dust can occur, monitoring soil contaminant concentrations in imported soil and raised beds is needed and, if necessary, soil decontamination for growing vegetables in urban areas.^[51]

CONCLUSION

More and more people depend on the ecosystem services arising from urban soil functions as earth's urban

population is growing. This increasing importance of urban soils for human well-being must be considered to support urban development. Supporting ecosystem services of urban soils include nutrient cycling and primary production. Further, urban soils are increasingly managed for food production and can contribute to C storage/regulation. Urban soils have a large potential for enhancement of local water storage, reduction in surface runoff, and flood control. Other regulating services of urban soils also increasing in significance are pollution attenuation and regulation of biodiversity. By best soil management practices, the inorganic and organic C stocks of urban soil can be enhanced, and urban agricultural production can be optimized. However, it is critically important to raise awareness among stakeholders for urban soils, their functions, and ecosystem services. The enhanced recognition of urban soils will support urban land use planning and management for enhancing the resilience of urban ecosystems.

Urban Wastewater for Irrigation: Heavy Metals

P.S. Minhas

K. Lal

Central Soil Salinity Research Institute, Karnal, India

Abstract

Wastewater primarily produced from municipalities and industries contains a variety of pollutants, and their usage has certain negative environmental impacts in the form of pathogens causing diseases, heavy metal accumulation, and soil salinization. In the developing countries, where wastewater is generally used for irrigating high-value crops like vegetables and fodders, the bioavailability and mobility of heavy metals is a matter of great concern as these parameters govern their uptake by plants and, in turn, food chain contamination. To limit the adverse effects, the guidelines for the treatment and usage of wastewater must be strictly observed. Due to resource constraints and prohibitive costs of conventional treatment in the developing countries, larger portions of wastewater are disposed either raw or after partial treatment in streams and land, or they are used for irrigation in peri-urban agriculture. Heavy metals, unlike organic pollutants, cannot be destroyed or converted into other harmless forms. Both phyto- and georemediation measures have been proposed for minimizing the concentration of heavy metals in the food chain. The afforestation, comprising trees of high economic value, efficient microbial strains, and wet lands, cultivation of remunerative but inedible crops, and application of organic and inorganic amendments, biofilters, conjunctive and regulated water use, are some of the useful strategies to mitigate or reduce the adverse impacts of wastewater irrigation.

INTRODUCTION

Sustainable management of soil and water resources in agriculture is the key and the most essential strategy for providing food and livelihood security. However, these natural resources are being contaminated with heavy metals because of the usage of large quantities of wastewater produced from continually expanding populations along with rapid industrial growth and urbanization. Wastewater is the water that has been used in domestic or industrial processes, and during the utilization process, its quality deteriorates because of excessive soluble salts, metals, metalloids, pathogens, and other organic and inorganic pollutants. Its use calls for sound management strategies to protect these resources from further degradation. Because of scarcity of freshwater especially in the arid and semiarid regions, even the highly polluted (e.g., selenium (Se), arsenic (As), cadmium (Cd), and chromium (Cr)) waters, including urban wastewaters, are being utilized for irrigation. The practice of wastewater irrigation is widely adopted by resource-poor farmers of the developing countries ignoring the potential health risks. Wastewater will also be increasingly used in the future because of higher freshwater allocation to industry and municipalities. This entry discusses some issues related to toxic constituents of waters, contamination of soils by heavy

metals, biomagnification in food chain by heavy metals, and some remedial measures.

URBAN WASTEWATER A SOURCE FOR LIVELIHOOD

With rapid urbanization and industrialization, huge volumes of the wastewater are generated, which need safe disposal. Only 15–25% of the water supplies to urban and industrial sectors are consumed and the remainder returned as wastewater. Peri-urban agriculture uses raw sewage, sludge, and industrial effluents in cultivated fields. These sources of water are used for irrigating high-value vegetables, fruits, food grains, fodder, and industrial crops. In poor economies, dependence on wastewater is a fact of life not a matter of choice. About two million hectares of agricultural land is irrigated with raw or partially treated, diluted, or treated wastewater.^[1] In closed basins, such as in some Middle Eastern countries, up to 70% of irrigation requirement is met using wastewater.^[2] Furthermore, the use of wastewater is increasing because of the combination of many interacting factors: water scarcity, assured irrigation, lack of alternate sources, proximity to market for perishable items, and affordable source of nutrient. Considerable increases in crop yields (up to 37%) in

different cropping systems have been obtained with wastewater use compared to those with freshwater and chemical fertilizer application. The increase in crop yields with the use of wastewater may be ascribed to added nutrients, e.g., the 10-cm wastewater irrigation per hectare supplies variable amount of nutrients: 16–62 kg nitrogen, 4–24 kg phosphorus, 2–69 kg potassium, 18–208 kg calcium, 9–100 kg magnesium, and 27–182 kg sodium, depending on the nutrient concentration and quantities of wastewater applied. However, it is seldom known which nutrients are the most beneficial and what their optimum quantities are, suggesting the strong need for periodic monitoring to avoid imbalanced nutrient supply.

SOURCES OF HEAVY METALS

Heavy metals [lead (Pb), Cd, Cr, mercury (Hg), nickel (Ni), Se, zinc (Zn), copper (Cu), and As] are the elements having a specific gravity of about 6.0 g cm^{-3} or greater and atomic weight more than that of iron (Fe). Not all the heavy metals are toxic, and in small quantities, many are essential to plant growth (Fe, manganese (Mn), molybdenum (Mo), Zn, and Cu). Although metals and metalloids are usually present in soil parent materials, there are several other anthropogenic sources (Table 1) such as mining, sludge production from industrial effluents, fossil fuel combustion, metallurgical industries, paints and pigments, and batteries. Among industries, Ni or chrome plating, engineering, tannery, textile, paper mill, power generating, and distillery are major contributors. Disposal of domestic, municipal, and industrial wastes is one of the major anthropogenic sources, which produces significant quantities of substances that harm environment. In addition to the abovementioned sources, agricultural activities, such as impurities in fertilizers, application of sewage sludge as a source of plant nutrients, pesticides, and irrigation with metal-rich waters, also contribute metal ions significantly to their total concentrations in soils especially in regions of intensive farming.

Treating the wastewaters before disposal as per guidelines is rather expensive. Thus, wastewater treatment comprises only 35% in Asia, 14% in Latin America, and negligible amount in Africa.^[3] The rest is disposed without treatment, thereby exacerbating the problem of soil and water contamination. It is always easier and less expensive to treat the wastewater at point source, i.e., industry level, than they are mixed resulting in large volumes of wastewater with complex composition and soil contamination. The stringent effluent emission standards formulated are rarely adhered by the industries causing contamination of soil–plant–animal continuum. In the developing countries, 70% of industrial wastes are dumped without treatment. Even after treatment, 40–60% of the heavy metals remain in wastewater. The magnitude of contamination depends on the amount and composition of wastewater disposed from

Table 1 List of anthropogenic sources of some selected metals and metalloids.

Chemical	Symbol	Major uses and sources ^a
Arsenic	As	Pesticides, animal feed additives, and manures from intensive animal production, desiccants, fossil fuel combustion, electronics, pigments and paints, medical uses, and groundwater
Cadmium	Cd	Electroplating, pigments for plastics and paints, batteries, sewage sludge, fossil fuel combustion, polymer stabilizers, waste disposal, and impurities in fertilizers
Chromium	Cr	Chrome-plated metals, pigments, electronics, fossil fuel combustion, impurities in fertilizers, wood preservatives, stainless steel
Copper	Cu	Fly ash, wind-blown copper containing dust, impurities in fertilizers, warfare and military training, waste disposal, medical uses, electronics, sewage sludge, wood preservatives, pesticides, and fungicides
Lead	Pb	Fossil fuel combustion, batteries, pigments and paints, polymer stabilizers, printing, sports shooting, warfare, and military training, waste disposal, impurities in fertilizers, and pesticides
Mercury	Hg	Pesticides, chlorine manufacture, medical uses, batteries, and electronics
Nickel	Ni	Alloy manufacture, electroplating, sewage sludge, batteries, and catalyst
Selenium	Se	Pigments, paints, printing, medical uses, and groundwater
Zinc	Zn	Metallurgical industries, electronics, pesticides, impurities in fertilizers, sewage sludge, pigments and paints, polymer stabilizers, printing, and medical uses

^aIn addition to mining of ore bodies in the earth's crust, smelting of scrap material, and weathering of soil minerals.

domestic and industrial sources, their mixing ratio, kind of raw material used by the industries, and degree of treatment used prior to disposal.

HEAVY METAL BIOAVAILABILITY AND CONTAMINATION OF FOOD CHAIN

Bioavailability and mobility of these metals rather than their absolute concentration in soils is a matter of great concern as these parameters govern the heavy metal uptake by plant and the attendant food chain contamination. The use of sewage and industrial effluents enhances the available metal status of agricultural soils by 2 to 100 times.^[4] Heavy metals are readily fixed in soils, and their contents

Table 2 Health problems associated with heavy metal accumulations in humans.

Heavy metal	Health problem
Cr, Cd, Hg, Pb, As, and Zn	Carcinogenic
As	Jaundice, reduced blood cells, and facial edema
Pb	Kidney damage, reduced reproductive capacity, disturbance in blood chemistry, and neurological disorders
Cr	Affects sugar metabolism
Ni	Skin cancer, asthma, and bronchial cancer
Zn	Affects elementary canal, metal fume fever or Monday morning fever, protein metabolism, and bronchial cancer
Hg	Affects kidney, heart, blood, and muscles
Fe	Blood chemistry, hemorrhagic gastritis, bronze diabetes, heart disease, and damage to kidney

are negatively correlated with soil pH and positively with organic carbon and clay content of soils. Although most of the added heavy metals accumulate in few centimeters of surface soil, leaching of contaminants below the plant root zone may, in the long run, affect the quality of groundwater resources. The actual threat depends on a host of factors including depth of water table, soil characteristics, and scale of heavy metals being added.

The indiscriminate and excessive use of wastewater causes a gradual heavy metal contamination in soil to the levels that might become toxic to crops. The heavy metal bioavailability depends on their potentially available amount, the activity in the soil solution, and the rate of

transfer from soil to plant roots. There is an unambiguous relationship between heavy metal accumulation in food crops and its source in wastewater from industries, municipalities, and domestic sources. Dietary intake of contaminated food and consumption of meat and milk obtained from the animal fed on fodder produced with wastewater are the major sources of food chain contamination, which have serious implications for the health and livelihood of the consumers and for the poor, in particular. Some of the important health problems associated with heavy metals are given in Table 2.

Crops also show preferential absorption and specificity toward heavy metals. Leafy vegetables (lettuce and spinach) and root crops are generally hyperaccumulator of heavy metals. The maximum accumulation seems to occur in roots followed by leaves, and this trend is very conspicuous in case of Ni. Thus, plants themselves act as filters to check the translocation of heavy metals from soils to consumable plant parts, i.e., seeds/fruits.^[5] This is especially true for Ni, Cu, and Pb. Further, Ni and Cu have added protective mechanism in terms of preemergence of phytotoxicity, where plants die or fail to grow much before they accumulate the metal ions to levels which are toxic to human beings (Table 3). However, Cd, which is carcinogenic and causes *itai-itai* disease (severely painful joints), escapes the “soil–plant barrier” and tends to accumulate at higher levels with the increasing Cd concentration in soils. The filtering at the root level may be less effective, but Cd tends to be partially excluded from fruits, as its contents are generally higher in foliar tissues than in fruits, seeds, and roots.

To contain heavy metal buildup, wastewaters should be evaluated for possible hazards. For safe crop production

Table 3 Recommended maximum concentration of heavy metals in irrigation water, maximum allowable limits, annual loading rates, recommended safe intake, and toxic limit.

Element	Recommended maximum concentration (mg l ⁻¹) in irrigation water ^a	Maximum allowable limit in soil (mg kg ⁻¹) ^b	Cumulative loading rate (kg ha ⁻¹) ^c	Recommended safe intake ^d	Toxic limit ^d
As	0.10	–	41	15–25 µg day ⁻¹	3 mg day ⁻¹ for 2–3 weeks
Cd	0.01	3–5	39	<70 µg day ⁻¹	200 µg kg ⁻¹ of fresh weight

and soil resource protection, the maximum permissible limits of heavy metals in irrigation waters^[6] and the maximum allowable limits and lifetime cumulative loading rates in soil have been proposed.^[7,8] These are presented in Table 3 including the recommended safe intake and toxic levels of heavy metal for an adult human being.^[9]

MANAGEMENT OPTIONS

Dealing with pathogens is much easier than with the heavy metals in wastewater. The industrial effluents must be collected separately and should not be mixed with the domestic wastewater. Polluter must pay, and therefore, industries must be encouraged to treat effluents at site and minimize its disposal.

Inorganic amendments (e.g., lime, phosphate, and alum), which form insoluble complexes or raise the pH, reduce heavy metal toxicity in soil or groundwater. Similarly, enhancing aeration of sewage-irrigated soils is important. These soils usually remain wet and anaerobic due to high contents of organics. Thus, drainage, regular tillage, and deficit irrigation should help in the formation of inactive oxidized forms of several toxic elements. Oxidized forms are generally less soluble and thus less available for plant uptake. Biosorbent organic materials with high specific area (e.g., saw dust, lignite, and peat) also reduce the heavy metal load of wastewater. Hyperaccumulating plant species, such as willow, mustard, tobacco, *Thlaspi*, and *Alyssum*, are the low-cost and plant-based phytoextraction measures. Even after the treatment, it must be ensured that wastewater is not applied to crops intended for human consumption. To avoid the contamination of the food chain, it is appropriate to use wastewater for cut flowers, aromatic grasses, cotton, and high-value forest trees like mahogany, mulberry, and poplar, which could be remunerative alternatives for wastewater use.

Wetland plants, such as *Eichhornia*, *Typha*, and *Phragmites*, have the capacity to remove heavy metals from wastewater. Under laboratory conditions, efficient fungi

and bacteria have been identified for absorption of heavy metals. Some of the georemediation technologies utilize chemical treatment for converting heavy metals into their insoluble minerals, bounding into the alumino-silicate portion of the soil or sediment, and immobilizing in the clay and smectitic lattice. A typical example is binding by specific nanoparticles, e.g., hematite, that have future potential to control the heavy metal pollution from diverse sources.

Abstract

Soil tillage and nitrogen (N) management are important to crop production. No-till (NT) can increase the soil carbon pools but reduce yield in some intensive agricultural regions by subsoil compaction and shallow root development. Subsoiling can reduce these problems caused by NT. Compared with conventional urea, use of controlled release urea (CRU) can significantly improve crop yields and also N use efficiency (NUE) while reducing environmental pollution. But the release of CRU is difficult to control because of numerous factors (e.g., the nature of the coating material, the type of CRU, and the agronomic conditions). The coating materials include sulfur, polymer, superabsorbent/water retention, and biocomposite, among which polymer has large potential. Subsoiling is performed at a 35–45 cm depth keeping a suitable interval between rows before or at the same time of sowing. CRU can be side-dressed or placed at 10 or 15 cm depth. Crops such as maize (*Zea mays*), wheat (*Triticum aestivum*), rice (*Oryza sativa*), barley (*Hordeum vulgare*), and canola (*Brassica napus*) under different conditions should use different controlled release period of CRU. Subsoiling can be used once after 2 to 3 years of NT to reduce the cost. Coupled use of subsoiling and CRU can improve yields by –4.1% to 63.7%. Additional research should focus on the optimal controlled release period of CRU for different crops in the field situation, low-cost and environmentally friendly coating material, and mechanization for using the subsoiling and CRU at the same time with sowing.

INTRODUCTION

Soil tillage and nitrogen (N) management are important to crop production.^[1] Tillage, which can modify soil's physical, mechanical, and biological properties by cutting, mixing, overturning, and loosening, has been an important technological development in the evolution of agriculture.^[2] Even well-graded soils are prone to close packing of soil particles and reduction of total porosity.^[3] Soil tillage was first used and continues to be the most common method to alleviate the soil compaction. However, any benefits of mechanical tillage are reduced by wheel traffic compaction by farm operations in many soil types and climatic regions.^[4] The wheel-induced soil compaction is widely recognized as a constraint to high crop yields when large agricultural vehicles are used for agronomic management.^[4] Thus, no-till (NT), also known as direct drilling and zero tillage, is increasingly being used in the United States, South America, China, and elsewhere,^[2] in which crops are sown

without any prior loosening of the soil by cultivation other than the very shallow disturbance (<5 cm) by the passage of the drill coulters after which usually >30% of the surface remains covered with residues.^[5] NT systems have a positive effect on soil structure, soil organic carbon (SOC) pool, and crop yield for a time. However, some negative effects on soil condition and crop growth have been observed after the long-term use of NT, which exacerbates the risk of subsoil compaction and shallow rooting.^[5] Soils compacted by vehicular traffic or natural processes often benefit from subsoiling, defined as tillage below a depth of 35 cm, by creating macropores that increase rooting and infiltration^[3,6] and enhance cereal production.^[7,8]

The increasing use of N fertilizer can significantly increase crop production. However, using too much N fertilizer could also decrease the N use efficiency (NUE) with a waste of precious resources, economic losses, and adverse impacts on the environment.^[9] Compared with conventional urea, use of controlled release urea (CRU) can

significantly improve crop yields, increase NUE, and reduce environmental pollution.^[10,11]

In general, coupled use of subsoiling and CRU increases the NUE and maize (*Zea mays*) grain yield.^[11,12] Yet, research data on the coupled use of subsoiling and CRU on diverse crops and regions are scanty. Thus, the objective of this entry is to collate, review, and synthesize the available research information on the coupled use of subsoiling and CRU for maize, wheat (*Triticum aestivum*), rice (*Oryza sativa*), barley (*Hordeum vulgare*), and canola (*Brassica napus*) in different countries.

SUBSOILING

Application of Subsoiling

Subsoiling is performed at a 35–45 cm depth keeping a suitable interval between rows before or at the time of

sowing (Fig. 1). To increase the SOC content, crop residues should be returned to the field prior to subsoiling. For some crops, such as maize, subsoiling can also be performed during early growth stages. In this scenario, the interval between rows should be the same as row interval of crops.

Reduce Cost of Subsoiling

In conservation systems, subsoiling is often conducted only in the row and referred to as in-row subsoiling or strip tillage. The strategy is to minimize surface disturbance and reduce the subsoiling cost.^[3] Despite the high cost of in-row subsoiling, significant gains in crop yield may be adequate to offset additional costs. There exists a range of options to reduce the cost of subsoiling, primarily through reductions in energy costs through fuel consumption, including performance of farm operations at field soil moisture, using subsoiler shanks for the designed depth, reducing frequency of subsoiling, and controlling vehicular traffic.^[3] In general, subsoiling is required once after 2 to 3 years of NT.^[13,14]

CONTROLLED RELEASE UREA

Choose Suitable CRU

An ideal CRU is coated with a natural or seminatural, environmentally friendly macromolecule material that retards urea release to such a slow rate that a single application to the soil can meet nutrient requirements for the crop growth. Thus, CRU enhances NUE and increases crop yields.^[15] The multistage diffusion model indicates that

Table 1 Use quantities and methods of CRU for crops.

Crop type	Region	Longitude and latitude	Soil type	Controlled release period	Used quantity	Used method	Yield increase	N use efficiency	References
Maize	China	36°10'N, 117°9'E	Cambisol	60–90 days	0.5–0.75 × commonly used	Banded at 10–15 cm soil depth	8~10%	Increase	[9,10,12]
Rice	India	23°59'N, 82°25'E	Sandyloam	100 days	105 kg N ha ⁻¹	Band application at about 2–5 cm	7.1~63.7%	Increase apparent N recovery fraction	[16]
Rice	China	36°09'N, 117°09'E	–	120–150 days	200 kg N ha ⁻¹	Placing with seeds	3~5.9%	Use less N fertilizers for greater rice grain yield	[17]
Winter wheat	China	34°55'N, 118°20'E	Calci-aquic Vertisols	90 days with 180 days	150 kg N ha ⁻¹	A mixture of 180 days and 120 release period of CRUs at the ratio of 3:7	6.5%	Reduced N fertilizer by one-third	[18]
Winter wheat	Canada	–	Clay loam	40 days	120 kg N ha ⁻¹	Seed-placed	Similar	Spring broadcast application of CRU was less effective than conventional urea	[19]
Barley, wheat, canola	Canada	–	The locations covered a wide range of soil types and panned a distance of 1600 km from east to west	60–90 days	Commonly used	Banded beneath the soil surface/broadcast	–4.1% to 22%	–	[20,21]

Note: –, not mentioned.

soil/irrigation water penetrates the coating and condenses on the solid fertilizer core followed by a partial nutrient dissolution (Fig. 2). The effects of CRU depend on numerous factors such as the nature of the coating materials, CRU type, and agronomic and edaphic conditions.^[15] Commonly used coating materials include sulfur, polymer, superabsorbent/water retention, and biocomposite.^[15] Among the newly developed commercial fertilizers, polymer-coated urea (PCU) is promising. In comparison with the large amount of conventional N fertilizers used in agriculture worldwide, total use of PCU is rather insignificant. The main obstacle to the wider use of PCU is the high cost associated with the complex manufacturing process and the expensive coating materials.^[22] Using the recyclable styrofoam waste as the coating material is economic and environmentally benign. Thus, it is important to choose a suitable CRU or PCU with consideration of the cost and release stage under the specific condition.

There are also differences between CRU and slow release urea (SRU), because the pattern of nutrient release of SRU is difficult to predict and remains subject to changes in soil type and climatic conditions. In contrast, the pattern, quantity, and time of release of CRU can be predicted, within some limits. Thus, CRU has some advantages compared with SRU.

Application of CRU

CRU can be side-dressed or applied at 10 or 15 cm depth after or at the time of subsoiling (Fig. 1). Further, CRU is most effective when placed at 15 cm depth. However, the growth rate of crop is slower during the seeding stage of crops when used with CRU because of its lower release compared with that of the conventional urea. Nonetheless, a higher growth rate is observed at a later stage.^[10] Split application of short controlled release period CRU, half at the sowing time and half side-dressed at tillering, can increase NUE,^[23] but also increases the energy input associated with split application. Thus, a blended application of 30–50% conventional urea and 70–50% CRU, and also a blended application of CRU with short and long controlled release periods, can be applied to improve crop growth for the entire growth period.^[20] By so doing, different crops under diverse conditions use different controlled release periods of CRU to enhance NUE (Table 1). Most importantly, the release in the field is >80% before the peak crop N uptake. For maize in North China, the favorable controlled release period of CRU is 60–90 days after seeding.^[9,10,12] For rice in India, the favorable controlled release period of CRU is 100 days but better for 120–150 days in China.^[16,17] In China, a mixture of 180- and 120-day release period of CRU at the ratio of 3:7 is benefit for winter wheat.^[18] In Canada, a controlled release period of 40–60 days is suitable for winter wheat, and that of 60–90 days is adequate for barley and canola.^[19–21] In general, using CRU can increase the yield and NUE for equivalent or lower rate of N application.

RESEARCH NEEDS AND FUTURE DIRECTIONS

Additional research is needed to identify an optimal controlled release period of CRU in the field situation for different crops under diverse soil and weather conditions. Mechanization of subsoiling and applying CRU at the time of sowing is very important for farmers' acceptance of the coupled use of subsoiling and CRU. Identifying economic and environmentally friendly coating materials for CRU is a high researchable priority.

CONCLUSIONS

There are positive coupled effects of subsoiling and CRU on crop growth, NUE, and environment. Such effects can increase the water and NUE and improve agronomic yields by –4% to 64% (Table 1). Thus, the coupled use of subsoiling and CRU is an important strategy in regions with limited resources of water and fertilizer, or in regions with the need to improve the water and N use efficiencies, which improves agronomic production.

Value of Soil to Humans

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

The soil plays a major role in nearly all human activities. Plants growing in the soil provide most of our food, material for clothing and building, and medicinal and industrial chemicals. The soil is a storehouse for many chemicals. Carbon is stored in the soil from decaying plant residues; both cations and anions (organic and inorganic) are held on exchange sites within the soil and held from leaching or releasing to the atmosphere. The soil is also the home for millions of microorganisms, which degrade organic wastes, and chemicals such as pesticides.

INTRODUCTION

The soil is the foundation upon which buildings, roads, and other structures are formed. The soil provides recreational sites for playing fields, golf courses, outdoor camping and picnics, wildlife habitat, and biological diversity.

The soil is inextricably linked to water and air. Water running off the soil or percolating into aquifers is used by animals and is cleansed and made fit for direct human consumption. It is also used for navigation and recreation. Water remaining in the soil can later provide water for plant use. The soil interacts with water to influence the atmosphere. Carbon from decaying plant residues is stored in the soil and thus does not contribute to atmospheric buildup of carbon dioxide (CO₂). The soil (and the water therein) interacts with atmospheric radiation and mitigates surface temperatures.

THE SOIL AS A PRODUCER OF FOOD AND FIBER

Approximately 11% of the land area, or 1461 million hectares of the world, are cultivated. In the United States, nearly 186 million hectares are cultivated.^[1] Crop and rangeland produce most of the food and fiber for the nation's human needs and for export. The United States' agricultural exports have exceeded \$50 billion.

The quality of the soil and landscape varies greatly. Nearly 19.8 million hectares of cropland are irrigated, mostly in the western states. Soil and landscape characteristics interact with weather to create a number of hazards for continued use of the land without serious degradation. Of all nature's hazards, erosion from wind and water is probably the most serious, although salinity, compaction,

acidity, and nutrient and organic matter depletion are also important.

Of the crops produced in the United States, those with the largest area include corn (29.6 million hectares), wheat (25.4 million hectares), soybeans (25.7 million hectares), hay (24.7 million hectares), sorghum (4.8 million hectares), cotton (5.2 million hectares), barley (2.7 million hectares), and oats (1.1 million hectares).^[1] Grain is used for direct human consumption, as feed for animals, and for the production of alcohol, sugar, and industrial chemicals. Cotton and other fiber crops are used for the making of cloth, and some seed crops are used for oil extraction and as feed for livestock. Many other crops are grown, including sugar beets, sugarcane, potatoes, canola, vegetables, fruits, nuts, and other products, for direct human consumption, animal feed, and specialty uses.

In the Western United States, about 239 million hectares of land is used for rangeland and pastures,^[1] producing much of the nation's beef, mutton, and dairy products. As with cropland, rangeland can be damaged from overgrazing, erosion, and other causes. Some of the rangeland are interspersed with forestland and cropland.

THE SOIL AS A PRODUCER OF FORESTS

The United States has almost 262 million hectares of forests,^[1] which are owned by the federal, state, and local governments and by private individuals and institutions. These forests are a source of wood and chemicals and are used for recreation and wildlife habitat.

Worldwide forests cover much of the landscape from the tropical rainforests to the boreal forests of the north and south hemispheres. Harvest and clearing procedures have been decreasing forestland in the tropics as well as in the United States.

Forests contribute a number of important functions for humans in addition to the production of wood and industrial products. Forests are a large sink for carbon, which is tied up in the vegetation and in the forest litter. Forests mitigate water balance, slowing runoff and releasing water slowly to surface and groundwaters. In mountainous areas, the forests store snow in the winter, and the melt water is slowly released to streams and groundwater in the summer.

THE SOIL AND ITS INTERACTION WITH WATER

Nearly, all atmospheric precipitation falls on the soil. As it strikes the surface, it either runs off the land and enters surface water bodies (lakes, streams, and wetlands) or enters the soil. If it enters the soil, it may be stored for later use by plants or may continue downward to enter groundwater. Thus, to a great extent, the condition of the soil (particularly at the surface) determines the ultimate disposition of water. Water moving across soil often carries with it eroded soil particles that may damage the soil for plant growth and may cause off-site damage leading to undesirable consequences. Sediment may be deposited in water supplies used for human consumption, or in road ditches, reservoirs, lakes, and other locations.

In 1992, the 48 contiguous states of the United States had approximately 50 million hectares of wetlands, down from 89 million hectares in 1780.^[1]

The soil is also an excellent sorbent for chemicals. Exchange sites for both cations and anions can remove chemicals from water as it percolates downward. After moving through the mantle of soil and underlying earth, water is usually purified, making it useable for human consumption. However, the capacity of soils to sorb chemicals varies greatly. Soils high in clay and/or organic matter usually have a greater sorbing capacity than sandy soils. Likewise, chemicals differ in their ability to attach to soil particles.

In the United States, as well as many other parts of the world, water supplies have sometimes been contaminated with excessive amounts of chemicals. Nitrates, phosphorus, and pesticides have been of most concern although chemicals from industry and human wastes are also of concern.

THE SOIL AND ITS INTERACTION WITH THE ATMOSPHERE

The soil has an important bearing on atmospheric conditions, particularly the atmosphere close to the ground. The color of the surface soil affects the balance between radiation sorbed by the soil or reflected back into the atmosphere. The water content of the soil determines how much of the radiant energy is used for heating the soil and air, or evaporating water from the soil.

In addition, the soil is a sink for carbon, nitrogen, and other gaseous elements that may be converted to volatile forms and released into the atmosphere. Carbon in the form of plant residues is continually added to the soil. Whether it remains in the soil as organic matter or is decomposed to CO₂ and released depends on the characteristics of the soil and its management. When the native soil was first brought into cultivation, the organic matter within the soil was usually drastically reduced. With better management, the organic matter is in many cases being increased. This has important global implications on the reduction of atmospheric CO₂ and lessening possible climate change.^[2]

THE SOIL AS A BASE FOR BUILDINGS, LAWNS, AND GARDENS

Many different types of structures are built on soils and the underlying materials. The different types of structures included are as follows: 1) shallow excavations consisting of trenches and holes usually dug to a maximum of 1–2 m; 2) dwellings and small commercial buildings; 3) roads and streets; and 4) lawns and landscaping. In addition, several types of sanitary facilities are built in the soil including: 1) septic tank absorption fields; 2) sewage lagoons; 3) trench sanitary landfills; 4) area sanitary landfills; and 5) daily cover for landfills. In 1992, the United States had nearly 21 million hectares of urban and built-up land.

Soil properties and site features determine, to a large extent, the performance of these structures. Type and content of clay, mineralogy of the silt and sand fraction, the kinds of adsorbed cations, erodibility, permeability, corrosivity, shrink–swell potential, available water capacity, and other behavioral characteristics affect engineering uses. Important landscape characteristics include depth to bedrock, soil wetness, depth to a seasonal high water table, slope, likelihood of flooding, natural soil structure, and soil density.

Of the 21 billion hectares of urban and built-up land, gardens and lawns comprise a considerable share. This land is usually highly managed for the production of fruits, vegetables, lawns, and ornamentals.

THE SOIL FOR USE IN RECREATION AND SPORTS

The soil is the material upon which most outdoor sports and recreational facilities are built. The facilities are as follows: 1) fields upon which a wide variety of sports are played (e.g., baseball, football, and soccer); 2) picnic grounds and hiking trails; 3) camping sites; 4) golf courses; and 5) parks and open spaces. The United States has 16,743 golf courses occupying almost 1 million

hectares of land. Several million hectares are probably devoted to picnic and local park areas.

Each of the recreation and sport uses requires either natural or engineered soil and/or landscape conditions. Sport fields usually require good drainage and the ability of the soil to support a grass cover. The soil is often graded to achieve the desired landscape features.

THE SOIL AS A MEDIUM FOR DIVERSITY

The soil is a medium in which a multitude of flora and fauna grow.^[3] Flora range from simple microorganisms to higher herbaceous plants, such as agricultural plants and trees. There are millions of microorganisms harbored in each gram of soil. Bacteria, actinomycetes, fungi, and algae are included. Many fauna (protozoa, worms, and arthropods) live in the soil, including higher animals such as mice, gophers, ground squirrels, and prairie dogs. Birds, such as the burrowing owl, access the soil through holes made by animals. Soil insects are an important source of food for many birds (e.g., worms for robins).

Because the soil is home to so many species, it is a repository for a great deal of genetic material. This material is a valuable resource that needs to be preserved. Under agricultural and highly managed forests, the genetic diversity of species is often limited and changed.

THE SOIL AS AN ARCHIVE OF NATURAL AND HUMAN HISTORY

Soil science can contribute to the understanding of natural and human history and thus provide valuable lessons for

management of natural resources. The detection of buried organic-rich horizons (Paleosols) and carbon dating of these horizons in relation to other horizons, as well as other chemical and physical properties, geomorphic, and landscape studies, are methods soil scientists use to reveal the past. Lowdermilk^[4] documents the deterioration of land through erosion, siltation, salinity, and nutrient depletion in the Middle East region. Lowdermilk estimated that at least 11 empires have risen and fallen in the 7000-year history of the Tigris and Euphrates Valleys. While the area supported large populations in the past, it depends on oil exports to sustain its people. The decline of the Mayan Empire in Central America more than 1000 years ago has been related to soil deterioration from poor management.^[5] Other examples of the decline of civilization as a result of soil deterioration are in Turkey and the Negev Desert in Israel.

Variability

Josef H. Görres

Department of Plant and Soil Science, University of Vermont, Burlington, Vermont, U.S.A.

Abstract

Spatial variability occurs at all scales—from micrometer scale (1–10 μm) relevant to microbial processes to continental scale (1000 km) relevant to the distribution of soil orders and climate change. The order of magnitude of the coefficient of variation of soil properties ranges from a few percent to greater than 100%. Jenny's soil-forming factors, such as climate, topography, organisms, parent material, and time, represent the fabric of the natural variability of soil that is modified by anthropogenic properties resulting in a complex distribution of soil characteristics. Very small-scale soil property variations may affect biological and chemical processes and may even explain soil ecological puzzles such as the high level of functional redundancy and diversity of soil biota. Spatial and temporal variations in soil properties may affect the spatial distribution of important soil processes. The spatial analysis of these variations is often done using semivariance analysis and mapping with kriging, an unbiased, optimal interpolation technique developed for estimating ore deposits from limited field data. Variable rate agriculture, in which Global Positioning System technology is used to map crop yield, uses spatial analysis to predict spatially explicit fertilizer applications to improve yield and lower environmental impacts. Spatial analysis is also used in environmental management, environmental modeling, and a multitude of research investigations. All applications need to consider the patterns and scale of variations in order to obtain accurate estimates of the variability of soil properties and processes.

INTRODUCTION

All soil properties, whether they be physical, biological, or chemical in nature, show considerable multiscale variability, ranging from microbial scales (1–1000 μm) to regional (10–100 km) and even continental scales (thousands of kilometers). Variability at all scales is high. The coefficients of variation (CVs—ratio of the standard deviation and mean) for individual properties may range from several percent to several hundred percent. Warrick^[1] classified variations of physical soil properties with CVs less than 15%, between 15% and 50%, and greater than 50% as low, medium, and high, respectively. Bulk density and porosity were classed as low, whereas electrical conductivity, hydraulic conductivity, and solute concentrations were classified as high variability. For biological properties, similar ranges are reported in the literature; e.g., CVs for phosphatase activity were reported as 39%.^[2] For forest soils, the CV for nematode abundance was of the order of 100% as compared to moisture and organic matter with CVs of 10–40%.^[3] Where earthworms are present, the CV of water percolation may vary from 10% to 100%.^[4,5] To make matters more complex, some soil properties and their variability change seasonally^[3] or indeed on a daily basis.

Soil scientists engaged in soil mapping, classification, and morphology may have to integrate over several scales to identify soil taxa. Soil taxonomy recognizes that translocations and translocations of soil materials connect soil

horizons in depth. Evaluating the 3-D variation of soil properties in combination at the pedon scale (meter scale) may thus produce thousands of unique profiles, each representing a soil series, the finest taxonomic resolution in soil classification systems and the pedology analog of species in Linnaean taxonomy.

Both natural processes and human activity contribute to the spatial variability encountered in soils. Jenny's equation of soil formation is the most commonly used model of pedogenesis that attempts to understand differences among soils in terms of five spatially variable factors. These five factors are responsible for landscape to continental-scale variations in soil properties.^[6] The mosaic of different soil series created by the superposition of Jenny's factors may be regarded as the fabric of soil variability which is further modified by land management.

Soil biological processes create very much smaller, microscale variations in properties other than those considered in soil classification. These variations can be tracked to particular origins;^[7] e.g., it has long been known that soil biota are more numerous in soil surrounding roots^[8] and burrows of soil animals^[9] than in the bulk soil. Microscale heterogeneity may cause the spatial separation of key nutrient cycling transformations that may drive many below-ground ecological processes.^[10,11]

Any record of the spatial distribution of properties is a snapshot in time. Soil processes are strongly dependent on meteorological and climatic forces and thus respond to temporal variations in temperature, precipitation, wind

speed, insolation, and relative humidity. Denitrification, the conversion of nitrate into a suite of nitrogen (N) gases, e.g., depends on the distribution of carbon at the microscale. However, denitrification is mainly an anaerobic process that is strongest under saturated conditions. Large rainfall events thus cause an increase in denitrification activity. Nitrification, on the other hand, is an aerobic process and thus occurs when soils are drying. As biochemical processes often occur at microsites, the diffusion of biochemical reaction products further links space and time.^[11]

Soil variability has practical consequences for experimental designs, farming, and the implementation and design of best management practices; e.g., precision farming employs variable rate technologies that strive to apply agrochemicals to soils based on georeferenced spatial variations of field fertility parameters. This may save farm resources and improve the environmental quality by reducing inputs of fertilizers and pesticides. Yet, environmental and economic impacts of variable rate agriculture may depend on many factors and it is not clear whether this technology always leads to a reduction in application rate on the field scale.^[12] In environmental application, land managers and soil evaluators often face questions associated with landscape-scale variations, such as how site-specific soil evaluations need to be when determining soil suitability for land use projects.

What all applications that account for the spatial variability of soils have in common is that the scale of variation ought to be a focus. The scale germane to an application will have to be isolated to design an appropriate sampling strategy and determine the volume (sample support) of an individual soil sample.^[13] Soil variability represents interesting challenges to soil scientists, making knowledge of spatial distribution of soil properties and processes paramount to the practice in both fundamental and applied pedology.

FACETS OF SPATIAL VARIABILITY IN SOILS

Soils, Soil Properties, Soil Processes, and Time

When discussing the spatial variability of soils, a distinction has to be made between the variability of soils, i.e., among taxonomic units, and soil properties, a measurable quantity. Pedologists classify terrestrial and subaqueous soils based on the vertical distribution of matter and its properties within a representative soil volume called a pedon.^[14] Each soil series thus has a unique sequence of horizons with specific diagnostic properties that are intertwined with spatially and temporally variable processes within and outside of the soil. Soil survey maps are quintessentially 2-D as the nature of a soil series is given by the relationship and interpretation of properties in the vertical as well as the horizontal dimensions of its profile. Soil classification relies on the spatial, 3-D arrangement of measurable and relatively stable properties within a soil profile.^[14]

However, stability and equilibrium are not one of the hallmarks of many soil properties. Spatial distributions change over time. Daily variations in soil moisture and temperature may engender rapid changes in food web dynamics and biochemical transformation rates responsible for much of the belowground decomposition and nutrient cycling. Variations also occur at seasonal and interannual scales. Even longer-term environmental variations relevant to climate and vegetation affect soil development in a way that may have tangible effects on soil loss.^[15] Among these decade-long cycles, space weather, in particular the 22-year cycles of the solar magnetosphere and the concomitant variation in cosmic ray fluxes, may be responsible for droughts such as the Dustbowl episode in the Southern United States in 1930.^[16] While devastating for farmers, these drought episodes are responsible for a spatial redistribution of top soil materials. However, even at a single point in time, snapshots of soils present observers with sufficiently puzzling spatial variability.

The importance of the dependence of variability on time is best illustrated by how changes in soil properties may affect the variability of soil processes. It is well known that small differences in soil moisture content may translate into large differences in soil processes. The affected processes are physicochemical and biological in nature. Moisture saturation at the center of aggregates in an otherwise dry soil may result in considerable denitrification rates.^[17] Also, only small differences in moisture or the presence and location of macropores in soils may result in large differences in water fluxes through the soil.

Factors of Soil Formation: Intrinsic Sources of Spatial Variability

Early soil scientists were intrigued by the differences in soils that they encountered in their travels. Dukochaev (1846–1903), Hilgard (1833–1916), and Jenny (1899–1992) formulated theories in which independent factors could explain geographic variations in soils.^[18] These factors are intrinsic or natural sources of variability. In an attempt to create a more quantitative foundation for soil science, Jenny's equation^[6] expressed the magnitude of soil-forming processes in terms of five variables or factors, namely: climate, parent material, topography, organisms, and time.

$$\text{Process} = F(\text{climate, topography, parent material, organisms, time}) \quad (1)$$

The five factors act on all soil-forming processes with each factor imbuing different qualities to the soil. Overlaying these qualities across the landscape differentiates among soil series, the spatial variability considered by soil taxonomy. At the continental scale, large-scale variations in climate, vegetation, and parent material give rise to characteristic patterns of soil orders, the coarsest soil

Global Soil Regions

taxonomic scale (Fig. 1); e.g., most Spodosols are found in northern, temperate climates with boreal, coniferous forests, where precipitation is high and glaciation has left deposits of sands, leading to distinct patterns of reduced and oxidized horizon environments (Fig. 2A). In contrast, Inceptisols have not developed very distinctive horizons due to a lack of time that the other factors have acted upon them. In Fig. 2B, an agricultural Inceptisol is shown with a horizon altered by plough action. This young soil (only thousands of years old) developed after the Laurentide ice sheet of the last glaciation melted and receded. In this soil, the combination of two parent materials, a fine silt mantle overlying glacial sand and gravel deposits, results in characteristic reduction oxidation horizons that dominate the spatial variability in the depth of the soil. The fine silt material may retain water long enough above the gravel deposit to reduce iron oxides, resulting in a horizon where the distinctive orange color of iron oxides is absent.

The five factors do not act independently, and Jenny's equation can thus not be understood as a linear algebraic

equation. Toposequences are a good example of the interrelationship between soil-forming factors at the landscape scale. A special toposequence called a hydrosequence is shown in Fig. 3. The landscape position along this hydrosequence not only determines elevation and, thus, the distance to ground water and the drainage class of the soil, but also determines vegetation, decomposition, and production rates of the ecosystems as the land surface slopes from an upland area into a wetland. Together, these factors are responsible for the variation of soils along the toposequence.

Action of *Homo sapiens*: Extrinsic Factors of Variability

Superimposed on the patchwork of intrinsic variation are extrinsic spatial patterns introduced by land management. At the landscape scale, the mosaic of agricultural fields (Fig. 4) may impose an additional variability of soils. In addition, within each field, management such as tillage and irrigation may introduce further variability at the field scale.

Fig. 2 (A) Spodosol at Hubbard Brook, New Hampshire. Distinct horization with a “bleached” E horizon above a characteristic dark area Bhs horizon, indicating the translocation of iron and humus from the E and O horizons. Provided by Dr. Joel Tilley of the Agricultural and Environmental Testing Lab at the University of Vermont. (B) Inceptisol at the Peckham Farm, Kingston, Rhode Island. A silt cap deposited over coarse sand gravel deposits created conditions that favor reduction of iron oxides within the silt horizon resulting in a white, colorless layer and a streak of white iron oxides at the contact between the silt and the sand and gravel.

Notably, extrinsic patterns may persist for many years even when the practice causing the initial variation is abandoned; e.g., ridge and furrow tillage in the 19th century may still have affected the crop yield pattern in 1911 at Rothamsted.^[19]

Apart from the desired patterns of fertilizer application and planting, the use of machinery causes compaction that

Fig. 3 Soil profiles along a toposequence vary by elevation or more importantly with the distance to the water table.

Fig. 4 Landscape-scale field planting pattern, an extrinsic variation contributing to the spatial variability of soils.

can also persist for many years.^[20] Likewise, the hoof fall of large grazing animals may affect soil compaction in pastures with characteristic spatial variations that depend on grazing pattern, paddock geography, and animal stocking rate. Dung deposition patterns in the pasture add to the variability of pasture soils^[21] and render the distribution of nutrient cycling processes uncertain.

These examples suggest that land management creates additional variability at the field scale. However, it can also be argued that land conversions may make soils more homogeneous; e.g., the conversion from a heterogeneous land use mosaic to large fields that support monocultures such as corn or sunflowers would smooth variations at the landscape scale while increasing heterogeneity at the field scale.

Variation at the Microscale

The patterns of soil heterogeneity observed by soil surveys, i.e., those that are caused by soil-forming factors, essentially integrate soil properties over the pedon that has a volume of several meters cubed. Yet, the diversity of processes at much smaller scale is apparent even when observing differences at the soil surface. The pattern of vegetation may reveal small-scale variations in soil properties, a fact that is used in plant indicator systems.^[22] Equally obvious at the soil surface are the patterns of excavation mounds of burrowing animals like ants and earthworms, which may coexist within centimeters of each other but have quite divergent microbial communities.^[23]

Very small-scale spatial variability is also regarded as the key to better understanding why soil faunal communities maintain high levels of diversity with much apparent functional redundancy.^[24] Pore networks comprise a diversity of pore neck and chamber diameters that allow access

Fig. 5 Micrograph of a thin section of sandy loam core showing the small-scale spatial variation in pore sizes. Pores are segmented in a light color. The network shows how the physical pore habitat varies even at the millimeter scale. The vertical extent of the image is 1 cm.

only to those organisms that fit into the pores. The variability of pore diameter at the micrometer scale is depicted in Fig. 5, where the light-colored segmented areas represent the pore network of a sandy loam collected in Rhode Island. The physical pore structure interacts with biologically active “spheres,” where soil organisms exert their influence on the soil and its microbial and faunal communities.^[7] Drilosphere and rhizosphere are the soils surrounding earthworm burrows and plant roots, respectively. The enrichment of the drilosphere with detrital resources welded to the burrow walls by earthworms and modification of the soil pore structure^[25] causes a large increase in biological activity.^[9,26] Similarly, resource enrichment can cause increases in microbial populations in the rhizosphere.^[8] Here, local photosynthate exudations prime soil biological and chemical activity.

Hattori and Hattori^[27] introduced the concept of microhabitats of protozoa and microorganisms that are located within soil aggregates, which Beare et al.^[7] called the “aggregatusphere.” With molecular techniques, it is possible to establish the spatial variability of microorganisms within single aggregates revealing great diversity at the millimeter scale.^[28]

The spatial distribution of pore spaces (also called the “porosphere”) and its partitioning into air and water-filled pores may select for specific soil organisms. Moisture controls the level of competition and predator–prey relationships that occur among soil organisms. Naturally, the relative fraction of air-filled and water-filled pores changes as soils dry and wet up, and thus, the mosaic of habitat of water and air-based soil organisms also changes. The concept of habitable pore space^[29,30] encapsulates this variability at scales of pore diameters ranging from tens to hundreds of micrometers. At these scales, soil pores are

microhabitats for protozoa^[27] and nematodes.^[25,31] However, there are different interpretations as to what happens to these habitable spaces when drying and wetting cycles rapidly alter their habitability for the aerial and the aquatic communities that inhabit soil pores.^[32]

The idea that microsites can significantly affect bulk soil processes suggests that measurement may be scale dependent. Parkin^[10] found that a soil core (100 cm³ scale) had very high denitrification activity. A single, small woodchip was isolated as the source of the high denitrification rate measured for the core. Parkin’s experiment demands that sampling support be considered in designs that are to estimate a soil property or process. Similarly, the moisture distribution within aggregates should be considered when examining denitrification in an otherwise dry soil.^[17]

Concepts of Variability

Variability is often conceptualized as the superposition of intrinsic and extrinsic factors, some of which were discussed earlier. However, there are other ways to look at soil variability. One such approach distinguishes between stochastic variations and deterministic variations that when added together are responsible for the variation in soil properties.

Deterministic variations are those that can be predicted from soil processes, and they may be spatially dependent at various scales. Spatial dependence is introduced by the translocation of matter and energy from one location to another or by the extent of large parent material deposits or even by vegetation patterns. Stochastic variations are those that cannot be predicted and are much like white noise and thus not spatially dependent. For spatial interpretations, the deterministic variables may have to be removed so that random variations can be properly characterized.

Webster^[33] argued that with sufficient knowledge about all soil processes, all variability is deterministic and that only incomplete knowledge and the sheer complexity of interacting soil processes may make variations in soil appear random. Notwithstanding philosophical argumentation about random and deterministic variations, apparent spatial dependence or independence may require different methods of estimating a central tendency and the variation about it.

One measure that is often used to describe variability is the CV, which measures the variation as standard deviation, s , standardized by the mean, μ :

$$CV = \frac{\sigma}{\mu} \quad (2)$$

The CV, however, requires that sample points are independent and may be falsely applied when there is any degree of spatial dependence. This casts some doubt on CVs estimated at different scales as soil properties may have different levels of spatial dependence at different scales.

Sampling and Quantifying Variability

Quantification of the variability of soil properties is more complex than it may appear. Even when designing the sampling method, important decisions need to be made. Apart from the classical equation for the number of samples that need to be taken to determine the mean of a sample distribution at a given confidence level and accuracy, the physical size of the sample support (the physical volume or mass of a sample specimen) becomes important as it will determine the smallest variations that can be resolved.

Sometimes, the nature of the assay will determine the sample support. For enzyme activity assays, only a couple of grams of soil is necessary. To get reliable enzyme activity information, several soil samples need to be homogenized and several replicates may need to be analyzed. The purpose of homogenization and analytical replication is to smooth small-scale variations and increase the certainty of estimation at a given scale. For measurements of bulk density, cores are taken that are typically 5–10 cm in diameter and 10 cm long. Variations that are contained within that volume are averaged out, or smoothed. Large-scale examples of spatial averaging come from remote sensing where luminosity is averaged over the area of pixels that are tens to thousands of meters in length. Selection of the satellite and sensor allows matching the scale of resolution with the research or management need. Spatial averaging is an essential tool not only for improving the reliability of data, but also focusing on the scale of the relevant variation.

Given a sufficient number of samples that were randomly collected, first-order statistics can describe soil variability in terms of statistical moments of the sample distribution: mean, variance, skewness, and kurtosis. This assumes that measured soil properties are independent of each other at the sample locations and for the scale represented by the sample support.

Many soil properties are spatially dependent. First-order, or classical, estimates of mean and variance can become biased when spatial relationships, the so-called second-order properties, are not taken into account. A second-order measure commonly used in soil science is the semivariogram, although other methods such as power spectra derived from Fourier harmonic decomposition have also been used.^[19] A semivariogram measures one half of the covariance between soil property values of sample pair classes that are classed by pair separation distances called lags. The further samples are apart, the greater their semivariance and the less related they are in space unless there are repeating patterns. Theoretically, the semivariance is limited to a maximum value that is reached when the lag exceeds the range of spatial dependence. To parameterize the semivariogram, an analytical semivariance function is fitted that best describes the variation. For spatially dependent samples, the semivariance functions increase as lag increases until the variance reaches a constant value called the “sill” (Fig. 5). The lag value at which the sill is reached

is called “range” and gives the maximum distance up to which the measured soil property is spatially correlated. Thus, for truly random variations, the sill variance is reached at lag 0. The semivariance parameter at lag 0 is also called “nugget variance.” It serves as a good aggregate estimator of error due to sampling uncertainty, unresolved variations, and analytical errors.

However, the estimates of second-order properties should be carried out with some care because just as there are rules for sampling spatially independent sample sets, there are rules for measuring the variability of spatially dependent samples. The Nyquist sampling theorem states that any variation potentially resolved by the sampling support needs to be sampled with a frequency of greater than twice the wavelength or characteristic length of the variation. If the rule is not obeyed, the signal cannot be adequately reconstructed or worse; the signal is misrepresented by an *alias* signal. For soil science, this means that under sampling a deterministic variation can result in a biased estimate of the mean and variance and potentially a misrepresentation of a pattern. An example for this is the soil moisture distribution across a plowed field (Fig. 6). The solid line in Fig. 7 shows the original, exhaustive 230-point sample set for soil moisture. The sample interval was 10 cm. The stippled line is based on 32 data points randomly selected from the original. This represents an average sampling interval of just under the wavelength, associated with a ridge and furrow pattern. The range of the original is 50 cm, but 90 cm for the undersampled variation. In addition to the overestimation of the range distance, the sill variance is overestimated by 30%. This error is not captured by the nugget variance, which usually

Fig. 6 Diagram of a semivariance function. There are three spatial parameters most often estimated with semivariance analyses. The distance, A_0 , where the data are no longer spatially dependent is called range. The maximum semivariance, $C + C_0$, is called sill and comprises the variance due to spatial variations, C , plus the nugget variance, C_0 , which is an aggregate measure of uncertainty due to analytical and sampling errors.

Fig. 7 (A) Exhaustive trace of soil moisture variation across a plowed field (solid line) with a randomly selected subset of data points (stippled line and triangular markers) at an average spacing just less of the wavelength of the ridge-furrow pattern. This is a violation of the Nyquist sampling theorem. The sampled variation mimics or aliases a variation with much longer spatial characteristics. (B) The semivariance function of the more exhaustively sampled moisture profile (solid line and diamond markers) has a spatially correlated range of 50 cm, while the semivariance of the aliased variation (triangular markers and broken line) is 90 cm long overestimating both the correlated range and the sill variance. Note that the nugget variance of the aliased signal is zero, showing that when signals are undersampled, the nugget variance is not a good indicator of the estimation error made.

Source: (A) Gorres, unpublished data.

is a good estimator of spatial estimation errors, but is zero for the undersampled moisture variation in this case.

For complete sample sets where sample points abut each other, the Nyquist theorem does not need to be invoked as the sample support would smooth out or integrate over any small unresolved variations. This kind of smoothing can be accomplished by taking several samples from each location, followed by combining and homogenizing the samples. Prior to analysis, satellite technology may also provide unabridged sample sets, where small-scale variations in luminosity are integrated over the pixel support. Apart from several specialized measurements (e.g., light detection and ranging), environmental satellite imagery is of low resolution and suitable only for large-scale investigations. Much progress needs to be made before remotely sensed data can replace *in situ* sampling for the analysis of some properties.

While it is clearly important to obtain as many samples as possible to satisfy needs for accuracy and improved inferential power, the cost of sampling and analysis often competes with the requirements of the central limit theorem and the Nyquist sampling theorem. Cost may prohibit high-frequency sampling across an area of interest. As a result, a bias toward long wavelength, variations may develop, exposing the estimates to aliasing of patterns. To include

and improve the estimates at shorter scales, random sampling schemes have been devised that include nests of closely spaced variations.^[26] In their study of physical and biological properties, 25×25 m plots were subdivided into twenty-five 5×5 m plots. A random core sample was taken from each plot. However, at five locations, nine samples were collected in 3×3 sample nests. The nested samples were 10 cm apart. In this way, variations at the meter and centimeter scale could be resolved.^[34]

Kriging

To estimate regional means of spatially correlated soil properties, the semivariance values are used in a spatial interpolation method called kriging. Kriging gives unbiased means and minimizes the error of estimation of regional parameters. The method was developed as a way to estimate the yield of ore deposits. In geological investigations, depositional patterns are large scale and aliasing may not be as much of a problem as in soils. Thus, the true error of the estimation of regional means with kriging depends strongly on the quality of the data collected and the care given to considering the spatial scale of patterns, even though kriging will mathematically minimize estimation error.

Some Applications of Spatial Estimation Methods

Spatial variations in soil properties are particularly important when the agricultural or environmental management requires targeted measures; e.g., nutrients need to be managed differently on a sandy soil than on a clay soil. Sometimes environmental risks can be better assessed when a spatially explicit distribution of soil properties is available. There is a wide range of applications that use the spatial variability of soils in order to optimize the estimates of properties or assess environmental risk.

One of the foremost commercial applications of the analysis of spatial patterns of soil properties is in variable rate agriculture, also known as precision agriculture. Improved productivity has been attributed to applying fertilizers at rates tailored to the previous year's yields or soil fertility status measured and spatially referenced using Global Positioning System. More fertilizer is applied in field areas where fertility is low than that in areas where it is high. Not only does this approach improve productivity and economic return, but it can also reduce nutrient loading to groundwater and surface water.

Losses of nutrients from fields are not only a risk to water quality but they also represent valuable farm resources. Spatial variations of soil properties are thus considered in farm nutrient management plans. Soil management tools such as the N leaching index and P index are used to estimate the risk of nutrient losses. In the United States, many states assign the nitrate (NO_3) leaching index based on the hydrologic group of the soil, a landscape-scale

measure of infiltration potential, as well as the regional rainfall patterns.

At much larger scales, the spatial variability of soil alkalinity has been incorporated into approaches to regulating acid air pollution. The critical load concept is central to this. The critical load of acid deposition is reached when observable changes in the ecosystem occur, i.e., when the acid challenge can no longer be buffered by the ecosystem. The critical load concept relates the atmospheric deposition of SO_x and NO_x to the rate of base cation release from soil minerals during weathering as well as other factors. Weathering is a soil-forming process, and thus, climate, parent material, organisms, and topography impose a spatial pattern, which has to be accounted for when mapping critical loads of acid deposition for a region. The typical resolution of critical load maps is one to several kilometers. Once critical loads have been determined, exceedance of the critical load for a map unit can be calculated and emissions can be regulated.

Increasingly, variations in soil properties are being used in combination with soil process models such as the Leaching Estimation and Chemistry Model (LEACHM) or Nitrogen Loss and Environmental Assessment Package in pollution risk assessment. For some applications, it is sufficient to treat the distribution of soil properties as independent. In this case, the means and measures of uncertainty of a particular soil process can be simulated by randomly selecting soil properties from their respective cumulative distribution functions as inputs to a soil process model. The repetition of these simulations gives a distribution of values for the soil process from which statistical moments can be derived; e.g., LEACHN, a submodel of LEACHM that estimates N and carbon dynamics, was parameterized using soil properties randomly selected from cumulative distribution functions of measured soil organic matter, bulk density, texture, and field capacity to simulate the mean of $\text{NO}_3\text{-N}$ in water extracted at a hypothetical production well.^[35] This approach also allowed an estimate of the probability that the water pumped at the well exceeded the Environmental Protection Agency drinking water standard of 10 mg $\text{NO}_3\text{-N/L}$ under different land use scenarios.

Watershed-scale model estimates of runoff and erosion have been improved using spatially explicit representations of the landscape. These models use remotely sensed data or spatially referenced soil survey data to establish a spatial context rather than assuming random distributions of soil property values across the landscape; e.g., the incorporation of soil information into a watershed model improved the estimate of storm hydrographs by accounting for delays in runoff contributions to stream flow.^[36]

CONCLUSION

Soils exhibit high levels of variability. CVs vary from less than 10% to greater than 100%. The magnitude of the CV

varies with the scale of measurement. Classical statistics can parameterize spatial distributions of spatial variations in terms of first-order statistical moments when the variations are spatially independent. However, more often than not, variations are spatially dependent, making it necessary to evaluate a spatial correlation between points. Any analysis of spatial heterogeneity that does not consider the properties of spatial patterns in the design of measurement and monitoring schemes will likely produce erroneous information.

Variability: Spatial

Brian Slater

School of Natural Resources, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Soils are highly variable in time and space. Scientists and environmental managers need to understand soil variability to design appropriate strategies to maintain the capacity of soils to provide essential environmental services. Variability also implies diversity, which can be viewed as a positive attribute of the soil cover. Pedometric techniques for quantifying variability and depicting its spatial characteristics are becoming essential tools for more precise and effective management of soils and productive enterprises that depend on them.

INTRODUCTION

Soil is a product of natural processes, which vary greatly in space and time, and is highly variable. It is this soil heterogeneity that makes it worthy of scientific attention. “Were the soil uniform, we should simply acknowledge the fact and shift our attention to something more interesting.”^[1] The major pedological endeavors—to understand the history of soil development, to classify the soil, and to depict soil geography—are all fundamentally directed toward knowledge of soil variability. Likewise, understanding and managing services provided by the soil resource for human benefit require knowledge of the nature of soil variability and the development of methods to measure, predict, and manage it.

Spatial variability has mostly been treated as a challenge to be controlled. Efficient farmers may wish to be able to apply consistent management across significant areas from year to year. However, soil variability may demand more adaptable management based on understanding how some soil properties (e.g., moisture-holding capacity) vary spatially within and between fields and how other properties (e.g., the actual amount of stored water) vary within and between growing seasons. Variability can be both a challenge and an asset.^[2]

VARIABILITY, DIVERSITY, AND HETEROGENEITY

It is well understood in ecology that diversity (the corollary of variability) creates the potential for stability, resilience, and a hedge against risk. In the longer term, a dryland farmer may benefit from the presence of contrasting soils (and soil properties such as soil moisture behavior) within a farm or field because rainfall may be highly variable and management-inconsistent. Having areas of light-textured soils may provide rapid crop response to lighter falls of rain; heavier soils may store more water during prolonged drought, and medium-texture soils may provide maximum

moisture availability and high yields in the best years. This diversity may result in efficient environmental function; e.g., areas of poorer infiltration may promote runoff, which is accepted in adjacent soils with higher permeability. Soil variability also factors into the diversity of natural and managed environments, of which soil is an integral part, diverse soils support diverse landscapes and a variety of habitats for living organisms and people.

Spatial variability implies that there are places where soil properties are best suited for specific purposes. An understanding of spatial variability leads to better matching soil management and soil characteristics to maintain the capacity of the soil to provide environmental services. Technology transfer and the scaling of known responses from sites, research plots, and fields to broader areas depend on knowledge of spatial variation. Agronomic research has evolved from attempts to control variability in field experiments to its embrace in precision agriculture.

SCALES OF VARIATION

Variability exists across the entire range of spatial scales. At the submicroscopic and microscopic scales, contrasts exist between various soil minerals, organic and living components, gases in the soil atmosphere, and the soil solution, creating soil fabric. Soil structure provides the architecture for soil water movement through pores and solid surfaces for adsorption and exchange of nutrients. At a broader scale, similar properties may cluster as a result of similar genetic materials and processes, and adjacent soils with contrasting properties are frequently arrayed together in landscapes.

ORIGINS OF SOIL VARIABILITY

Many early observations of soil variability are related to differences in plant yield and vigor and contrasts in mechanical and physical properties of soil as a material for

Fig. 1 Aerial image of farm fields in Central Ohio, showing soil variability associated with contrasts in drainage conditions.

construction (Fig. 1). People needed to understand and predict these contrasts to improve crop production and safely fabricate buildings and roads. With the development of pedology in 19th-century Russia,^[3] the idea that soil developed according to the interaction of factors of soil formation provided a basis for understanding differences in the morphology and behavior of soils observed in the field. Observations that similar attribute values and soil qualities clustered spatially and were often related more or less predictably to other environmental features such as types of geological materials, landform and landscape positions, patterns of surface and subsurface water movement, and vegetation provided impetus for soil survey efforts.^[4]

Patterns include chronosequences related to surfaces of contrasting geomorphic age and stability, lithosequences related to varying types of parent material and bedrock, toposequences resulting from contrasting relief on similar parent materials, and biosequences responding to changes in flora and fauna. These differences provided the basis for early forms of soil classification and the development of geographic units delineated on soil maps. As well as these more serial (anisotropic) patterns, repetitive patterns of varying regularity in some soils result from directional forces. Examples include gilgai microrelief in Vertisols, tree throw, and cryoturbation features.

Geologic materials and transported sediments exhibit major differences in composition and structure and associated physical and chemical properties related to their lithologic origin and history of development and transport. The weathering and reworking of materials and products further add to the diversity of soil-forming precursors. Geomorphic differentiation results from the effects of contrasting hydrologic conditions, microclimate effects

including solar radiation differences, and variable erosion and accretion on surfaces of variable stability. Finally, biological activity within and on the soil contributes to soil evolution and variation.

Many of these spatial contrasts are visible or measurable directly, although patterns present at short or long ranges have become clear with the advent of remote sensing techniques, instruments, and imagery, from microscopes to aerial photography and the variety of satellite-based imaging platforms. Much soil variability exists in the third dimension and hence can be best understood only through excavation of the soil in the field. Over time, soils develop horizons, approximately horizontal layers that reflect specific patterns and processes of soil genesis. Even at a single site, soil properties and functions vary spatially in the vertical direction. Variability can be greatly different between different horizons and for different attributes within an individual horizon.^[5]

Human influences have modified natural patterns and established new forms of heterogeneity. Land clearing and forestry operations, tillage, fertilizer and amendment applications, accelerated erosion and compaction, earth shaping, drainage, building of roads, structures, and other impervious surfaces have altered natural patterns.

SYSTEMATIC AND RANDOM VARIATION

While highly variable, considerable orderliness exists in the pattern of soil cover. This orderliness contributes to the utility of soil survey and classification.^[6] To be captured on soil maps, there must be contiguity of entities with similar properties and some external expression of boundaries (e.g., locations of rapid, coincident variation of multiple attributes). Conventional soil survey relies on the presence of relatively homogeneous patches of similar soil with a limited range of attribute variation, with more variation at and across boundaries.^[7] However, in reality, abrupt changes may be rare (dependent on scale); soil attributes often have a more continuous, gradual, or noisy spatial distribution.^[7,8] Conventional soil survey depictions of discrete polygons (*choropleth* maps) most consistently capture abrupt patterns of soil variation, where there is a strong correlation between soil properties and sensible external expression of boundaries such as changes in vegetation, landform, and remotely sensed image patterns. Even where a particular attribute changes abruptly in geographic space, other attributes may vary independently or at different rates or different scales. Soil surveys based on external classification systems rather than “taken from the landscape” locally^[6] delineate impure map units. Individual bodies of soil (pedons and polypedons) are not expected to exhibit the same range of variation in all attributes defined by taxonomic classes, and the geographic projection of these classes will frequently not yield large contiguous polygons, but rather smaller patches interspersed with

either contrasting bodies or collections of sites where one or more attributes lie outside the range defined by the class limits.^[9] Many studies of soil variability by pedologists have concentrated on defining the variation within mapping units.^[10] Mapping systematic variation may be useful for spatial generalizations and interpretations.

MEASURING SOIL VARIABILITY

While pedologists have concentrated on understanding systematic variability, the aim of many agronomic researchers has been to control or eliminate it. Where the soil population can be assumed to meet traditional requirements of normality, randomness, and independence,^[11] variability can be measured by parametric statistics such as the coefficient of variation (CV):

$$CV = \frac{s}{\bar{x}} \times 100 \quad (1)$$

where s is the standard deviation and $\bar{x}$ is the mean.

The CV has frequently been used to compare variability of collections of samples such as those taken from within different mapping units for the purpose of comparison. Samples for comparing variability of map units have often been taken on linear transects or according to various “design-based” sampling schemes aimed at gaining sufficient information to estimate mean attribute values with known levels of confidence.^[12]

Systematic soil variability may often be difficult to categorize deterministically with sufficient confidence, and variation may appear chaotic. Patterns may be obscured or impossible to measure and predict because of random or unidentified sources of variation or unavoidable measurement error. The need to quantify and propagate uncertainty in models of soil spatial variability has provided impetus to the growing field of soil science known as pedometrics.

Spatial clustering of similar attribute values is evidence of spatial dependence. Geostatistical methods have been widely used to model spatial dependence stochastically. Models that treat the soil as a product of random spatial processes have proved successful in providing a basis for measuring, mapping, and managing soil spatial variability.^[13]

This geostatistical model is often stated:^[14]

$$Z(x) = \mu + \varepsilon(x) \quad (2)$$

where $Z(x)$ is a *regionalized variable*, μ is the mean, and $\varepsilon(x)$ is a random component or *residual*.

The residuals are considered to be spatially (auto) correlated; sample locations of greater proximity are more likely to have similar attribute values. The *semivariance* is a quantity that represents the degree of spatial autocorrelation:

$$\gamma(h) = \frac{1}{2} E\{[Z(x) - Z(x+h)]^2\} \quad (3)$$

where $\gamma(h)$ is semivariance, E is the expectation, and h is a vector representing the distance between observations (the *lag*).

In practice, the semivariance is estimated from samples; e.g., for a linear transect of n sites, the semivariance at lag h is:

$$\hat{\gamma}(h) = \frac{1}{2(n-h)} \sum_{i=1}^{n-h} \{Z(x_i) - Z(x_i + h)\}^2 \quad (4)$$

where h is the distance separating pairs of sample sites.

Spatial dependence can be expressed by a function that relates the correlation between pairs of observations to the distance between observations. The function that relates the semivariance to the lag is the *semivariogram* (or just *variogram*; Fig. 2). Graphical realizations of the variogram are often used to gauge the structure of spatial variation. Typically, the semivariance increases with increasing lag, frequently reaching a maximum (the *sill*) at a finite lag distance (the *range*) beyond which spatial dependence cannot be measured. The variogram typically does not pass through the origin, as it would be for a purely continuous process,^[1] but has an ordinal intercept known as the *nugget variance* that is most often interpreted as a random uncorrelated short-range error component, perhaps a result of measurement inaccuracy. Models can be fit to the function produced from a series of observations (e.g., by an automated procedure such as minimizing the sum of squares). The fitted relationship can then be used to interpolate attribute values for locations between sample stations, a technique known as *kriging*. Kriging uses a linear weighting based on the lag distances from measured points and weights determined to minimize the variance of the prediction error.

The value of an attribute Z at a location x_0 is:

$$\hat{Z}(x_0) = \sum_{i=1}^n \lambda_i Z(x_i) \quad (5)$$

Fig. 2 Schematic semivariogram for soil properties.

where $Z(x_i)$ are a series of point observations and λ_i are weights.

Kriging is considered an optimal interpolator in that it minimizes prediction error (for well-behaved models) and is unbiased. Kriging has been used to estimate attribute values at unvisited sites, to make continuous maps, or to estimate values over defined blocks (block kriging). Methods have been developed to incorporate prior data and covarying attributes (cokriging), to map occurrences of attribute values meeting defined criteria (indicator kriging), and to simulate multiple realizations of stochastic outcomes.^[15]

MANAGING VARIABILITY

Soil diversity means that we cannot know everything everywhere about soils. As a result, there is uncertainty and hence a need to sample, interpolate, and map variation. Soil variability demands differential, site-specific management.

Soil management needs to be responsive to the variation in the resource to minimize economic and environmental costs. Soil managers and conservationists have long understood that contrasts in soil characteristics result in differences in the capacity of soils to produce and provide services and also demand differences in treatment. Soil and land capability maps and farm conservation plans are examples of simple spatial depictions of soil variability and consequences for management.

Increasing recognition of short-range variability has fostered the development of precision farming techniques, which aim to direct management responses to specifically matched soil and environmental conditions at within-field scales. Precision management involves collection of information on soil spatial and temporal variability and the tailoring of inputs and practices to the capacities and demands of the resource, with the aim of reducing costs, increasing production, and minimizing leakage of inputs (such as fertilizers) from the system.

CONCLUSION

Soils are highly variable in time and space. Scientists and environmental managers need to understand soil variability to design appropriate strategies to maintain the capacity of soils to provide essential environmental services. Variability also implies diversity, which can be viewed as a positive attribute of the soil cover. Pedometric techniques for

quantifying variability and depicting its spatial characteristics are becoming essential tools for more precise and effective management of soils and productive enterprises that depend on them.

Abstract

Soils rich in particles with amphoteric surface properties in the Oxisols, Ultisols, Alfisols, Spodosols, and Andisols orders are considered to be variable charge soils. They have developed under intensive weathering in subtropical and tropical regions or from volcanic ash parent material. The term “variable charge” is used to describe organic and inorganic soil constituents with reactive surface groups whose charge varies with pH, and ionic concentration and composition of the soil solution. The variable charge is developed on the surface groups as a result of adsorption or desorption of solid-like ions that are constituents of the solid phase, i.e., H^+ , and the adsorption or desorption of solid-unlike ions that are not constituents of the solid phase. Variable charge soils are heterogeneous charge systems. Variations in relative proportions and chemical composition of the major mineral soil constituents of highly weathered soils and volcanic ash soils influence the surface reactivity, which is the key factor controlling nutrient availability. The coexistence and interactions of soil particles and colloids with net opposite surface charges confer interesting properties with complex attributes with respect to physical and chemical behavior, compared to homogeneously charged soil systems of temperate regions. In this entry, the mineralogy, chemistry and management of variable charge soils are reviewed and discussed, focusing on the chemistry of these fascinating soil systems. Because surface charge properties are of central importance in the management of variable charge soils, different management practices that may manipulate charge characteristics and retention capacities are discussed.

INTRODUCTION

Soils rich in particles with amphoteric surface properties in the Oxisols, Ultisols, Alfisols, Spodosols, and Andisols orders^[1] are considered to be variable charge soils (Table 1).^[2] The term “variable charge” is used to describe organic and inorganic soil constituents with reactive surface groups whose charge varies with pH and ionic concentration and composition of the soil solution. Such groups are the surface carboxyl, phenolic, and amino functional groups of organic materials and surface hydroxyl groups of iron (Fe) and aluminum (Al) oxides, allophane, and imogolite. The hydroxyl surface groups are also present on edges of some phyllosilicate minerals such as kaolinite, mica, and hydroxyl-interlayered vermiculite. The variable charge is developed on the surface groups as a result of adsorption or desorption of ions that are constituents of the

solid phase, i.e., H^+ , and the adsorption or desorption of solid-unlike ions that are not constituents of the solid phase.

Highly weathered soils and subsoils (e.g., Oxisols and some Ultisols, Alfisols, and Andisols) may undergo iso-electric weathering and reach a “zero net charge” stage during their development. They usually have a slightly acidic to acidic soil solution pH, which is close to either the point of zero net charge (PZNC)^[4] or the point of zero salt effect.^[4] They are characterized by high abundances of minerals with a point of zero net proton charge (PZNPC)^[4] at neutral and slightly basic pHs; the most important being Fe and Al oxides and allophane. Under acidic conditions, the surfaces of these minerals are net positively charged. In contrast, the surfaces of permanent charge phyllosilicates are negatively charged regardless of ambient conditions. Variable charge soils, therefore, are heterogeneous charge systems.

Table 1 Global areas and percentages of suborders of the soil orders with variable charge soils.

Orders	Suborders	Area [km ² (×10 ³)]	Subtotal [km ² (×10 ³)]	Proportion (%)	Subtotal (%)
Alfisols	Aqualfs	836		0.7	
	Cryalfs	2,518		1.9

The coexistence and interactions of oppositely charged surfaces or particles confer a different pattern of physical and chemical behavior on the soil, relative to the homogeneously charged soil system characteristic of temperate regions. In some variable charge soils (Oxisols and some Ultisols developed on ferromagnesian-rich parent materials), the surfaces of phyllosilicates are coated to a lesser or greater extent by amorphous or crystalline, oppositely charged nanoparticles of Fe and Al oxides. These coatings exhibit a high reactive surface area and help cementing larger particles with one another. Because of these electrostatic interactions, stable microaggregates that are difficult to disperse are formed in the variable charge soils.

Most highly weathered soils have reached the “advanced stage” of the Jackson–Sherman weathering sequence that is characterized by the removal of sodium, potassium, calcium (Ca), magnesium (Mg), and Fe(II), the presence of Fe and Al polymers, and very dilute soil solutions with an ionic strength (IS) of less than 1 mmol L⁻¹. The interpenetration or overlapping of the diffuse double layers on oppositely charged surfaces may occur in these dilute systems. These diffuse layer interactions may

decrease the magnitude of the effective charge, i.e., the counterion charge,^[5] and may also inhibit the natural tendency for acidification of the soils.^[6] In addition, salt adsorption, which is defined as the simultaneous adsorption in equivalent amounts of the cation and anion of an electrolyte with no net release of other ions into the soil solution, appears to be a common phenomenon in these soils. They act as cation and anion exchangers and as salt-sorbers. The magnitude of salt adsorption depends strongly on initial IS in the soil solution and the presence of appreciable amounts of oppositely charged surfaces. The overlapping of the diffuse layers on oppositely charged surfaces may be responsible for the salt adsorption in variable charge soils.^[7,8]

A.D. Noble,^[22,33] and R.K. Xu.^[6,8,35–38] This entry is mainly based on publications by these authors.

MINERALOGY OF VARIABLE CHARGE SOILS

The most important mineralogical components in variable-charge soils are kaolinite, Fe oxides, and gibbsite in Oxisols; kaolinite, hydroxyl-interlayered vermiculite, muscovite, Fe and Al oxides, and minor amount of smectite in Ultisols (quartz in the sand and silt fractions); kaolinite and smectite in the highly weathered Alfisols (mica and Fe oxides in smaller abundances and quartz and feldspars in the coarse fractions); minor amounts of mica, chlorite, kaolinite, and vermiculite in the clay fraction of Spodosols (orthoclase, plagioclase, mica, pyroxene, and amphibole in the sand fraction; and quartz and traces of plagioclase in the silt and sand fraction); and allophane, imogolite, poorly crystalline Fe oxides (e.g., ferrihydrite), volcanic glass (which is a mixture of aluminosilicates and traces of ferromagnesian minerals), and secondary silicon (Si) minerals (cristobalite, opaline silica) in Andisols.

The clay fraction mineralogy of variable charge subsoils is mostly dominated by the quintet: kaolinite, gibbsite, goethite, hematite, and short-range-order minerals (e.g., allophane, imogolite, and ferrihydrite). However, the contents and proportions of mineralogical constituents, particle size distribution, and specific surface areas are different in unlike soils. As a result, they manifest a significant diversity in their properties. Variable charge subsoils are likely to have one of the following five mineralogical characteristics when they reach the apparent steady state during their development.^[13,29] 1) large amounts of kaolinite and crystalline and less reactive Fe and Al oxides, mainly hematite and gibbsite (typical examples are some Oxisols from Africa, South America, Australia, and Southern China); 2) large amounts of kaolinite and very reactive Fe and Al oxides, mainly Al-substituted goethite and gibbsite (typical examples are Ultisols from the Southeastern United States, South America, Africa, and Southern China); 3) large amounts of extremely reactive short-range-order minerals such as allophane, imogolite, and ferrihydrite (typical examples are Andisols from Indonesia, Pacific Rim countries, and New Zealand); 4) almost monophase mineralogy dominated by kaolinite and small amounts of Fe oxides (typical examples are some Ultisols from Southeastern United States, Southern Africa, and Brazil and some Oxisols from Hawaii); and 5) almost monophase mineralogy dominated by not very reactive Fe and Al oxides and, in some cases, Ni oxides (typical examples are some Oxisols from New Caledonia and Jamaica). Because kaolinite, Fe and Al oxides, and allophane are the most typical mineralogical components of these soils, they are treated in more detail below.

Kaolinite is a 1:1 phyllosilicate that has an Al octahedral sheet and a Si tetrahedral sheet. Each layer of kaolinite has

two surfaces: the surface of oxygens of the Si tetrahedral sheet and the surface of hydroxyls of the Al octahedral sheet. Both these surface groups are fully charge satisfied and have low reactivity. However, the edges of kaolinitic particles have unsatisfied and quite reactive, singly coordinated aluminol and silanol variable charge groups. Kaolinite has the lowest surface charge (about 1–5 cmol_(c) kg⁻¹) among common clay minerals because of the relatively small number of isomorphic substitutions in its structure. It has a PZNC at pH about 3.5 and a PZNPC at pH about 5; it also has a low specific surface area (between 5 and 39 m² g⁻¹) and, commonly, a pseudohexagonal plate shape.

Fe and Al oxides are the most important sources of variable charge in soils of the humid tropics. Their amphoteric surfaces are capable of sorbing and desorbing protons depending on pH and IS of the soil solution. Their PZNPC is at pHs over 7, so they have a net surface positive charge under acid conditions typical for variable charge soils. Goethite and hematite are the most important Fe oxides in highly weathered soils. The substitution of Al for Fe is more frequent in these soils. This affects surface charge as it generally results in a lower degree of crystallinity, a smaller particle size, and hence a significant increase in surface area and sorption capacities. They occur as nanoparticles with different shapes and high specific surface area.

Under the name of allophane are included a group of aluminosilicate minerals with primarily short-range structural order that occur as spherical nanoparticles 3–6 nm in diameter, with a chemical composition of silica and alumina. The specific surface area varies between 700 m² g⁻¹ and 900 m² g⁻¹. Allophane may have both permanent and variable surface charge. The variable charge results from protonation and dissociation of surface aluminol and silanol functional groups, with aluminol groups having negative, neutral, or positive charge and the more acidic silanol groups having either neutral or negative charge. Allophane interacts effectively with soil organic matter (OM).

CHEMISTRY OF VARIABLE CHARGE SOILS

With respect to the origin of the surface charge, the soil minerals common to variable charge soils can be grouped in^[1] constant surface charge and^[2] variable charge soil minerals.

Constant Charge Minerals

In constant surface charge minerals, the permanent charge is due to imperfections in the lattice structure resulting from isomorphous substitution. The substitution is generally restricted to a lower valence element for those with a higher valence, e.g., a divalent Mg for a trivalent Al, resulting in a negative charge at the particle surface. This negative charge is then compensated by the accumulation at the crystal surface of the counterions that are oppositely charged,

hydrated or non-hydrated ions. As those defects occur in the interior of the crystal lattice, the resulting surface charge is permanent and it is not influenced by pH, electrolyte concentration, dielectric constant and ionic composition of the aqueous phase, and temperature. In this case, the fundamental equation of the Gouy–Chapman theory of the double layer may be written as follows:^[28]

$$(8.6 \times 10^{-3} \text{ RT } \epsilon \epsilon_0 \text{C})^{1/2} \sinh \frac{ze\Psi_0}{2\text{RT}} = \sigma_{\text{permanent}} = \text{const.}$$

where

$\sigma_{\text{permanent}}$ = permanent surface charge (cmol kg^{-1});
 Ψ_0 = surface potential (volts);
 e = electronic charge ($1.6021 \times 10^{-19} \text{ C}$);
 z = valence of the adsorbed ions (dimensionless but carries charge);
 C = electrolyte concentration (M);
 ϵ = dielectric constant of aqueous phase (78.5 at 298 K);
 ϵ_0 = permittivity of free space ($8.854 \times 10^{-12} \text{ C V}^{-1} \text{ mol}^{-1}$);
 R = molar gas constant ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$); and
 T = absolute temperature (K).

This equation implies that surface potential, however, is affected by all the factors mentioned above, i.e., electrolyte concentration, temperature, and dielectric constant and ionic composition of the aqueous phase. The most important constant surface charge minerals are the 2:1 phyllosilicates with variable basal spacing, such as vermiculites and smectites. Smectites, if present, only occur in small abundances in highly weathered tropical soils. In volcanic ash soils, they are usually present in minor amounts but occasionally in substantial or dominant amounts.

Variable Charge Minerals

In variable charge soil minerals, the surface charge is created by the adsorption of the potential-determining ions (pdi) or other specifically adsorbed ions onto the surface. The charging process requires the presence of these ions in the soil solution in sufficient quantities for adsorption to occur. Variable charge or amphoteric constituents in soils may have organic and/or inorganic origin.

The origin of charge on the organic fraction is due to ionization of active carboxyl, amino, and phenolic functional groups as a result of their protonation or deprotonation as it is shown in the following reactions:

Acidic functional groups are the main source of the exchange capacity in the organic fraction. Carboxyl groups

probably account for the highest proportion of the cation exchange capacity (CEC) of soil OM at pH 7.^[32]

In the highly weathered tropical soils, inorganic constituents with amphoteric surfaces are Fe and Al oxides, clay minerals with edges with broken bonds, and complexes of Fe and Al with OM. Again these functional groups acquire their charge by either protonation or deprotonation. The surface charge may also originate from surface complex formation of specifically adsorbed ions. The Gouy–Chapman equation of the double layer theory for symmetrical electrolyte may be written in this case as follows:

$$(8.6 \times 10^{-3} \text{ RT } \epsilon \epsilon_0 \text{C})^{1/2} \sinh \frac{ze}{2\text{RT}} (\text{const.}\Psi_0) = \sigma_{\text{variable}}$$

The surface potential does not vary with electrolyte concentration, dielectric constant of the aqueous phase, and temperature. The surface potential is also independent of ionic composition of the aqueous phase, if the ions are not pdi or have not the ability to form inner sphere complexes with the surface reactive groups. Surface potential changes with pH or when activity of ions that may potentially be specifically adsorbed changes in the aqueous phase. We should emphasize here that most soil variable charge surfaces such as Fe and Al oxides, hydroxides, and oxy-hydroxides do not obey the Nernst equation, which means that their surface potential changes by less than 59 mV for each unit change in pH.^[27] The fundamental assumption involved when the Nernst equation is derived is that the activity of the pdi on the surface remains constant as the surface acquires charge. This is not true in the case of Fe and Al oxides, which have few charged surface groups at their PZNPC. The interface between the solid Fe or Al oxide surfaces and the aqueous phase in contact with them in variable charge soils is depicted in Fig. 1.

MANAGEMENT OF VARIABLE CHARGE SOILS

Variable charge soils are generally acidic and have low CECs and the propensity to fix phosphorus (P) and boron.^[40] They support tropical rain forests that have an intrinsically tight nutrient cycling capacity. Soil OM that effectively acts as a slow-release nutrient source mediates this cycling. When these ecosystems are disturbed and placed under agronomic production, OM is rapidly lost due to continuous mixing of surface soils, and consequently, there is a rapid decline in fertility. This decline is associated with an accelerated acidification and a reduction in the CEC, thereby limiting the ability of the soil to hold cationic macronutrients and micronutrients, which are rapidly lost through leaching. Insufficient negative charge in the subsoil will also lead to poor root development, making plants incapable of using subsoil moisture during droughty periods. On the other hand, these soils develop appreciable anion exchange capacity (AEC) under acidic conditions, which retain otherwise leachable anions such as nitrate and

Fig. 1 Schematic presentation (not in proportional dimensions) of the electrical double layer at the Fe oxide: aqueous solution interface. The 0-plane is defined by the location of protonated or deprotonated surface sites. The β -planes extend from surface to the centers of specifically adsorbed anions or cations. The d-plane corresponds to the beginning of the diffuse layer of counterions and coions.

Source: Modified after Brown and Parks.^[39]

sulfate particularly in subsoils. In addition, some experiments seem to show that adsorption of low-affinity cations, such as Ca, reduced surface charge and even resulted in charge reversal. Due to these intrinsic characteristics, surface charge properties are of central importance in the management of variable charge soils (Table 2).

The surface charge characteristics and retention capacities in variable charge soils may be manipulated via:

1. Increasing OM content: The CEC and amounts of nutrients stored in highly weathered and volcanic ash topsoils are mainly related to the OM content. OM content decreases progressively with time under cultivation in these soils, and the loss of OM through oxidation or erosion occurs especially during prolonged cropping; this reduces the ability to supply nitrogen, P, and sulfur and to retain cations in exchangeable form.^[32] Agricultural practices aiming at increasing OM content and decreasing OM removal through erosion are therefore important. However, under humid tropical conditions, increasing soil OM and maintaining it are problematic as it is rapidly mineralized.

Source: Photos courtesy of E. Van Ranst, Ghent University, Belgium.

2. Decreasing PZNPC in soils: One way of lowering PZNPC in soils would be to increase the OM content in the soil. OM has a low PZNPC ($\text{pH} \sim 4$), thus contributing to decreasing the soil PZNPC. The large organic anions may also be adsorbed on positively charged surfaces, reducing the amount of positive charge in subsoil. The adsorption of organic anions of low molecular weight organic acids secreted from plant roots and produced through the decomposition of plant residues in variable charge soils can also decrease PZNPC of the soils through increasing negative surface charge and decreasing positive surface charge.^[35] Phosphate (PO_4) anions may react with the surface of soil colloids by adsorption reactions and reverse charge. Consequently, in situations where it is not possible to build up OM levels, inorganic soil amendments such as PO_4 could be used to lower the PZNPC. However, this is a rather expensive intervention in tropical countries.
3. Changing soil pH: Increasing the soil pH through the addition of liming materials will result in the precipitation of phytotoxic Al and an increase in CEC. The increase in soil pH enhances the soil capacity to hold and supply essential plant nutrients. However, in order to increase the soil pH to 6 or above, as is often advocated in permanently charged temperate soils,

Table 2 Constraints and management options for variable charge soils.

Constraint	Management options
I. Soil acidity—Al toxicity	Routine prophylactic applications of calcitic or dolomitic limestone. Soil pH should be maintained at pH 5.5 to reduce the risk of Al^{3+} toxicity. If manganese (Mn) toxicity is suspected as pH should be raised to 6.0. Overliming decreases the availability of P, boron, zinc, and Mn and results in yield declines. In addition, there is a decline in soil structure. Judicious use of acidifying nitrogenous fertilizers will minimize acid generation through the conversion of NH_4^+ to NO_3^-. Alternatively, the use of NO_3^--based sources of nitrogen would eliminate any acid generation associated with mineralization. Retention of crop residues and organic matter to increase the pH buffering capacity. Application of organic materials with high ash alkalinity is an alternative source of alkalinity where conventional liming materials are not available. Application of biochar to increase soil pH and exchangeable base cations and decrease soil exchangeable Al^{3+}. Application of gypsum increases levels of soluble Ca^{2+} and reduces levels of toxic Al^{3+} in subsoils.^[41] Subsoil acidity can be corrected through a combination of growing deep-rooted acid-tolerant grass species (<i>Andropogon spp.</i>) and in combination with leaching, and nitrate fertilizations will result in the remediation of subsoil acidity.
II. Low cationic retention from fertilizers	Regular small amounts of inorganic fertilizer should be applied to reduce the risk of leaching loss and increase efficiency. In addition, fertilizer additions will increase the ionic strength, thereby increasing the surface charge. Increasing the negativity of the exchange complex can be achieved through increasing the soil pH or decreasing PZNPC. Lowering of PZNPC can be achieved by sorption of large anions onto particle surfaces, thereby masking a portion of the positive charge. Continued regular applications of organic matter and biochar will increase the CEC of soils as well as effectively lower the PZNPC. In situations where organic matter levels are not possible to increase, inorganic soil amendments such as phosphate and silicates could be used to lower PZNPC. When increasing the negative charge of these soils, the anion exchange capacity will decline, thereby reducing the ability of these soils to retain anionic species such as nitrate.
III. Strong fixation of anionic fertilizers such as P	Try to reduce the reactivity of surfaces for PO_4. This could be achieved by increasing the amounts of colloids with low affinity for PO_4 fixation, the addition of other anions that compete with PO_4, and the application of organic matter. In addition, sources of silica, ground basalt, volcanic ash, and Ca silicate can be used. Banded applications of inorganic P fertilizers. Use of rock phosphate under acid conditions
IV. Low nutrient-supplying capacity	The application of superphosphate may promote the release of nutrients through the breakdown of silicate minerals through the formation of H_3PO_4. Si deficiency on highly weathered soils can be rectified through the addition of silicate materials.

enormous inputs of lime are required, which is inefficient because of the high buffering capacity of these soils; it may also result in micronutrient deficiencies. By maintaining these soils at a pH of 5.5, phytotoxic Al is eliminated from the exchange complex, and a significant amount of negative charge is generated. Frequent small applications of lime are advocated to achieve this objective. This may also be done through the application of basic rock dusts that act as a slow-release source of Ca and Mg as well as being a liming material.^[19] In addition, laboratory and field experiments with ground, calc-alkaline pyroclastic materials from the Nyiragongo volcano (Democratic Republic of Congo) added to highly weathered soils have shown that the negative surface charge may increase in these soils.^[31] Nevertheless, it is of practical importance to maintain the pH of variable charge soils at levels

sufficiently high to precipitate Al and to increase CEC especially in Ultisols of the humid tropics that contain 2:1 clay minerals with variable basal spacing. Andisols are generally characterized by low amounts of exchangeable Al, and overliming them commonly results in manganese and zinc deficiencies. One should be careful when applying management techniques that aim at changing the pH in soils because an increase in soil solution pH would increase the CEC but decrease the AEC. An increase in CEC would help agricultural production, but the corresponding decrease in AEC would decrease the capacity of soils, especially subsoil, to retain contaminant anions such as nitrate. Management practices that contribute to increasing the negative permanent charge in soils are, therefore, more desirable in some cases. The application of permanently charged clay minerals (i.e., bentonite) has been

shown to permanently increase the negative charge component and productivity of degraded Oxisols.^[22] Gypsum can also increase negative charge.^[42]

4. Increasing both soil pH and CEC through incorporation of biochar: Biochar is a carbon (C)-rich, trendy yet ancient soil amendment, produced by slow thermochemical pyrolysis of biomass materials. It is formed when organic materials, such as livestock manures, sewage sludge, crop residues, and compost, are heated at temperatures between 300°C and 1000°C under relatively low oxygen conditions. It is possible that the application of biochar to soils would help in the long-term maintenance of the soil's organic C content and soil fertility. In addition, biochars can have an unusually high CEC, which increases the adsorption capacity of soils for selected nutrients and toxic heavy metals decreasing their mobility. Biochars normally have alkaline pH and can be used to ameliorate soil acidity and to increase the pH buffering capacity of acid soils.^[37] Biochar is stable and difficult to decompose in soils compared with its feedstock and thus a better amendment for acidic variable charge soils than plant residues.

CONCLUSION

Variable charge soils have unique surface charge characteristics and mineralogy. Kaolinite and sesquioxides are the most common minerals in the clay fraction, and little or no weatherable minerals are present in the silt and sand fractions. Variations in relative proportions and chemical composition of the major mineral soil constituents of highly weathered soils and volcanic ash soils influence the surface reactivity, which is the key factor controlling nutrient availability. Nutrient management of these soils effectively dictates small and frequent applications of inorganic fertilizers. The most typical properties of variable charge soils are low effective CEC, high effective AEC, low OM, low available water-holding capacity, high hydraulic conductivity, very stable microaggregates, high P appreciable AEC that significantly retards the adsorption, and relatively high point of zero charge. A rational management can be obtained by trying to change the nature of the colloidal surfaces, leading to an increase in CEC. This might be achieved by blocking positively charged sites, e.g., application of P fertilizers and silicates and incorporation of young pyroclastic materials and biochars, or by a better management of the OM and a more efficient erosion control.

Abstract

Vertisols are clay soils in which the clay fraction is dominated by swelling clay minerals, mainly smectites. Vertisol formation is favored by a warm climate with alternating wet and dry seasons. Vertisols have a characteristic morphology resulting from the swelling and shrinking of the clays upon changes in moisture content. Soil properties have a distinct impact on agricultural practice. The soils are used for rain-grown and irrigated cropping. They require specific agronomic techniques and land use systems.

INTRODUCTION

Vertisols are dark-colored clay soils with a specific structure and with surface characteristics and deep cracks when dry. The soil swells upon wetting and shrinks when drying. Clay percentages, by definition 30 or higher,^[1] are often over 60. Smectite minerals (montmorillonite and others) dominate the clay fraction. Soil parent materials are either silty/clayey deposits, rich in smectite minerals, or weathering materials from mainly basic rock types (marl, limestone, basalt, and basic igneous rock) that produce swelling clay minerals upon further weathering. Both the formation of the parent materials and the formation of the typical Vertisol profile are favored by a warm climate with alternating wet and dry seasons.

The preservation of basic ions during weathering and soil formation is essential for the formation of smectites, and this explains the occurrence of most Vertisols in poorly drained, often level terrain. Vertisols developed from basic rocks generally occupy sloping positions; external drainage is normal, but internal drainage is sufficiently slow and leaching restricted, so that the smectite clays are formed. Most Vertisols are found between 45° north and south latitudes in a semiarid to subhumid environment. The largest areas are in India (79 mha), Australia (70.5 mha), and Sudan (50 mha). Vertisols cover extensive areas in several other African countries, the Americas, and China and smaller areas in Southern Asia and Southern Europe (Table 1). They are also described in arctic semiarid regions, e.g., in Canada and the United States.^[4] Vertisols and other soils with vertic properties may cover up to 320 mha worldwide.^[3] Because of their physical properties and the resulting problems with soil and water management, Vertisols are correctly labeled “problem soils.” This should not, however, distract from the fact that with proper management Vertisols are among the most productive soils in semiarid agriculture.

Problems are also met in the transfer of research results and technologies from other soils to Vertisols. The

applications of techniques that are effective in non-swelling soils have often produced misleading results. Concepts such as field capacity, permanent wilting point, available water capacity (AWC), and bulk density have a different or more restricted meaning, and Vertisols sometimes require specific laboratory or field investigations.

SOIL PHYSICAL AND CHEMICAL PROPERTIES RELEVANT TO AGRICULTURAL USE

Soil Structure

Most structural features of Vertisols have seasonal aspects. This implies non-permanency of their porous system, a striking difference contrasting with rigid soils.^[5] When dry, most Vertisols have subangular and wedge-shaped angular peds, increasing in size with depth. Cracks, some centimeters wide at the soil surface, extend to depths between 60 and 100 cm. Cracks are commonly obscured at the surface by fine crumb to granular soil aggregates (Fig. 1). This surface mulch is developed because of repeated wetting and drying.^[6] Other Vertisols develop a hard surface crust, i.e., 2–3 cm thick.

Factors That Influence Soil Structure

Clay percentage and amount of swelling
clay minerals

Generally, there is a positive correlation between clay percentage and percentage of smectite clay minerals in the clay fraction and degree of structure development.^[7] Vertisols with over 60% of mainly smectite clay are well structured: they have a surface mulch, a finely aggregated surface soil, a blocky structure with wedge-shaped peds, and many slickensides in the subsoil. Vertisols with relatively low-clay and high-sand contents are poorly structured.

Table 1 Distribution of dark clay soils.

Countries and areas	Estimated extent (mha)
<i>Angola</i> : valleys of the Cunene and Cunbango, region of Catete, and southwestern part of the country	0.5
<i>Argentina</i> : mainly in the northeastern part of the country in the province of Entre Rios, in the northeastern department of Buenos Aires, in south Corrientes, Santa Fe, and the Eastern Chaco	6.0
<i>Australia</i> : mainly in Queensland (Darling Downs), northern plains, east-central part and coastal areas of the Northern Territories, patches in south Australia (near Adelaide), northwestern Australia, and in Tasmania	70.5
<i>Benin</i> : northern part of the country and in the region of Divo	0.1
<i>Bolivia</i> : mainly in the eastern part of the country, Livingstone, and Tuli; probably large areas around the Okovambo and Makarikari swamps	2.0
<i>Botswana</i> : west of Livingstone and Tuli; probably large areas around Makarikari swamps	0.5
<i>Brazil</i> : southwestern and western regions of Rio Grande do Sul (Bage, Uruguaiana, Alegrese, and d. Pedrito districts); in the western parts of the country bordering Uruguay, Paraguay, and Bolivia; in north eastern Brazil	4.5
<i>Burkina Faso</i> : Souron Valley; poorly drained basin deposits spread over the country	0.4
<i>Cameroon</i> : Logone Chari basin and part of the Chad Basin; penepplain of Kaele and Marona region	1.2
<i>Chile</i> : depressional areas associated with non-calcic brown soils in Santiago and O'Higgins provinces and also associated with Prairie and Chestnut soils in Magallanes Province	0.5
<i>China</i> : Central China	12.0
<i>Ecuador</i> : hilly lowland and valley bottoms in western part of the country (provinces of Guayas, Manabi, Esmeraldas)	1.0
<i>Egypt</i> : Nile delta	1.0
<i>Ethiopia</i> : rift valley and Ethiopia plateau	13.0
<i>Ghana</i> : mainly Accra, Ho-Keta, and Winneba Plains; scattered patches near Kpandu, Kwamen, and Kwesi	0.2
<i>India</i> : Central and South Central Deccan plateau (parts of Bombay, Hyderabad, and Madhya Pradesh state)	79.0
<i>Indonesia</i> : mainly in Central Java (Semarang, Demak, Bojonegoro, Surabaya area), East Java and Lesser Sunda Islands (Lombok, Timor, Sumbawa, and Flores)	1.8
<i>Ivory Coast</i> : in northern part of the country and in the region of Divo	2.8
<i>Kenya</i> : Athi Plains near Nairobi and other areas	Unavailable
<i>Lesotho</i> : Drakensberg	2.3

(Continued)

Table 1 Distribution of dark clay soils. (Continued)

Countries and areas	Estimated extent (mha)
<i>Madagascar</i> : some valley depressions in the western part of the country and on the uplands in the western and northwestern part	0.8
<i>Malawi</i> : Chyre valley and areas around Nyasa and Chilwa lakes	1.6
<i>Mali</i> : Niger valley, and a large area along the borders with Mauritania	0.7
<i>Marocco</i> : mainly in the northwest (Gharb) and in the doukkalas (south of Casablanca); scattered spots	0.2
<i>Mozambique</i> : alluvial plains of the Limpopo and Inkomati rivers and surrounding uplands; Zambezi valley upstream of Tete	1.1
<i>Namibia</i> : probable occurrence in the Caprivi Strip along the Cubango river and around the Etosha Pan	0.7
<i>Niger</i> : central Niger valley and several scattered patches	0.1
<i>Nigeria</i> : northeast Bornu and Benoue river basin	4.0
<i>Paraguay</i> : depressional areas in basaltic and limestone plateaus of the eastern region; in the Paraguay river basin and large areas in the Chaco region	1.5
<i>Portugal</i> : depressional area on diorite and limestone in Alentejo	0.1
<i>Senegal</i> : Senegal valley, lowland of the northwest	0.2
<i>Somalia</i> : in the plains extending between the Juba and the Shebeli rivers	0.8
<i>South Africa</i> : Bushveld and Springbok Flats (Transvaal)	2.1
<i>Sudan</i> : region between the White and the Blue Nile extending east of the Blue Nile into Ethiopia and covering an area west of the White Nile: widespread in South Sudan, Bahr el Ghazal, Upper Nile, and Equatoria Province	50.0
<i>Swaziland</i> : mainly in the Middelveld, eastern Lowveld and Lebombo areas	0.2
<i>Syria</i> : Jezireh and basaltic plateaus, south of Damascus	0.6
<i>Tanzania</i> : valley of the Mayowsi and Malagarasi, Great Ruaha valley areas near Tendigo swamps and Rukwa lake; scattered upland areas	7.0
<i>Togo</i> : in the northern part of the country and in the Mono valley	0.1
<i>Uganda</i> : valley of the Semliki, areas near George, Albert, and Edward lakes, areas in the eastland northeast of the country	1.7
<i>Union of Soviet Socialist Republics</i> : compact Chernozems in the Caucasus between Krasnodar and Grozny	0.8
<i>United States of America</i> : "Blackland" in Central Texas from the Red River bottomland on the north	18.0

They have a thin surface crust and a coarse blocky structure with few large slickensides in the subsoil.

Organic matter

Organic matter in Vertisols ranges from 5 to 100 g/kg and is commonly between 5 and 50 g/kg.^[8] Organic matter functions, such as binding nutrients and water, are, in Vertisols, provided by active clay surfaces. Organic matter in the soil (crop residues, weeds, decaying roots, and waste compost) stimulates biological activity and supplies organic colloids to form organo-mineral composite aggregates. Organic matter has an ameliorative effect on notably the physical properties of the soil such as structure development and aggregate stability,^[7,9,10] and it reduces dry bulk density, penetration resistance, and shear strength and increases saturated hydraulic conductivity, porosity, and soil water and nutrient retention.^[11–14] Blanchart et al.^[15] mention the important role of

roots and earthworms in restoring the physical properties of degraded Vertisols.

Coulombe, Wilding, and Dixon^[8] consider clay-organic complexes to be fundamental to the formation and stability of soil aggregates. Research in Australia, summarized by McGarry,^[7] has shown that an improved structural stability was linked with the larger amounts of the “active fraction,” i.e., the more labile types of organic matter rather than with the total amount.

Cation exchange capacity, exchangeable cations, and electrolyte concentration of the soil solution

Vertisols generally have high cation exchange capacities and high base saturations. Commonly, calcium or magnesium dominates, depending on the parent material.^[16] In Vertisols with a high proportion of divalent cations, the clays are flocculated and the soils well structured. Vertisols with high exchangeable sodium (sodic soils) have surface crusts and widely spaced cracks enclosing compact large aggregates. They tend to disperse upon wetting.^[8]

Coupling electrical conductivity (EC) with the exchangeable sodium percentage (ESP) or sodium absorption ratio is necessary to predict clay dispersion.^[17] Crescimanno et al.^[18] found that at low cationic concentration, physical soil degradation occurs in a 2–5 ESP range, and that at increasing ESP, soil behavior appears as a continuum. Heber, Shedaksharappa, and Patil^[19] observed that hydraulic conductivity decreased and dispersion increased with increasing ESP and decreasing electrolyte concentration. The presence of some minerals such as gypsum can overcome the dispersing action of sodium and flocculate soil particles.^[20]

Climate and landform

The length of the rainy season, the amount and intensity of annual rainfall, and the frequency of wet–dry cycles impact the soil structure of Vertisols. In Sudan, the strongly self-mulching soils with fine aggregation are in the northern arid part of the Vertisol belt.^[21–24] Generally, these soils have free carbonates and gypsum; calcium is the dominant cation. In higher-rainfall regions, increased soil leaching results in lower pHs, whereas there are no free carbonates and gypsum; mulch development is reduced and soil structural aggregates are coarser. Crusty Vertisols are restricted to sodic spots in irrigated fields and topographic low situations with standing water after heavy rains.^[25]

SOIL CONSISTENCE

Soil consistence directly impacts tillage operations. Generally, Vertisols are sticky and very plastic when wet, hard to very hard when dry, and friable when moist. Moist consistence is the optimum for tillage operations, but unfortunately the time span that the soil is moist is usually short and its

Fig. 1 Cracks and surface mulch in a Vertisol.

occurrence is uncertain because it depends on often erratic rainfall.

Sodic Vertisols are smearier when wet, more easily dispersed, and extremely hard when dry. Sandy Vertisols have lower plasticity and stickiness as compared to modal Vertisols, whereas the large aggregates—or large clods resulting from tillage—are extremely hard and do not crumble into a mulch upon wetting and drying.

SOIL–WATER RELATIONS

Infiltration and Hydraulic Conductivity

Infiltration into a dry surface mulch or prepared seedbed is rapid. Subsurface moistening is rapid as long as water can enter open cracks. When cracks close after wetting, infiltration is greatly reduced. Water in cracks passes through fissures between ped surfaces (including slickensides) and through biopores into the soil matrix.^[26] Infiltration is promoted by the retention of crop residue or fallow weeds, either as a cover or plowed into the soil.

It was observed in furrow irrigation^[27] that water in cracks was 10 m ahead of water on the surface. Shrinkage fissures connect cracks, so that irrigation water passes through quickly. If a rainy season starts with heavy storms, wetting through cracks and connecting fissures is rapid. Lighter rains give a more gradual surface wetting whereby crack entrances are closed, and cracks fail to function as preferential pathways.^[5]

The hydraulic conductivity in a moist Vertisol is slow, whereas in a wet Vertisol, it is very slow. Measuring hydraulic conductivity in Vertisols is problematic, as there is no horizontal wetting front and pore-size changes with the moisture content.^[28]

Moisture Retention

Vertisols have a relatively high moisture retention at all water potentials. The AWC defined as the difference between the water contents at 0.033 MPa (0.33 bar; field capacity) and 1.5 MPa (15 bar; permanent wilting point) has been reported as 110–250 mm for the surface 1 m depth.^[29] At field capacity and wilting point, a positive correlation was found between water content and both clay percentage and amount of smectite minerals in the clay fraction.^[30,31] Table 2 gives chemical and physical characteristics, including water contents at field capacity and permanent wilting point and the AWC of a typical Vertisol in Sudan.

Kutilek^[5] found that Vertisols with ESP between 10 and 20 showed a drastic increase of the lower boundary of available water and suggested to abandon the concept of the 1.5 MPa wilting point in sodic Vertisols and use the direct experiment on plant wilting instead. He concluded that AWC in Vertisols cannot be measured by procedures empirically derived in non-vertic soils. Farbrother^[32] proposed to consider the saturated water content as the upper boundary of AWC in Vertisols of the semiarid zone.

The concept of plant available water capacity (PAWC) was introduced by Gardner et al.^[33] PAWC is defined as the amount of water that can be extracted from an initially fully wet soil by a crop before a chosen stress symptom is observed.^[34] PAWC varies with crop, root development, depth of rooting, and other soil properties and gives a more realistic figure for the storage of soil water that is available to the plant roots in a given situation than does AWC (Fig. 2). Kirchhof, Smith, and Hyson^[36] mention the effect of soil textural class, soil moisture, and soil depth (an overburden effect) on readily plant available water.

Table 2 Chemical and physical characteristics of a Typic Pellustert (S81 FN 835–9) from near Damazin, Sudan (11°45'N and 32°47'E).

Groundwater in Vertisols?

At the bottom of cracks, infiltration may stagnate and form transient perched water tables. Groundwater tables in Vertisols cannot be defined as lateral movement of water is negligible.^[37] However, a groundwater level could develop in a more permeable substratum underlying a Vertisol. Dowling et al.^[38] report on groundwater tables at the interface of Vertisols and the underlying basalt. Groundwater tables changing with the seasons are observed in Vertisols in Israel (see Ben Hur et al.).^[39]

SOIL PROPERTIES AND THE AGRICULTURAL USE OF VERTISOLS

Soil Management and Tillage Operations

The management of Vertisols under dryland conditions is discussed by Kalane,^[40] the sustainable management of Vertisols in African countries by Syers, Penning de Vries, and Nyamudeza,^[41] and soil management of irrigated cotton by McKenzie et al.^[42]

Deep tillage of dry Vertisols requires high draft. Plowing or harrowing wet Vertisols is almost impossible. A moist soil can be tilled by hand or by animal-drawn and machine-drawn implements.

Plowing, especially deep plowing, has several disadvantages for soil quality: soil structure is destroyed,^[43] soil faunal activity (earthworms and termites) is disrupted, and the continuity of pores are reduced. This has a negative effect on water and air permeability. The use of heavy

machinery compacts wet soils and plowing them forms shear planes or plow pans.^[6,27,44,45]

The surface mulch that develops in many Vertisols after repeated wetting and drying is a great asset because it forms a natural seedbed and promotes the infiltration of rain or irrigation water. Structure regenerates by the process of self mulching. Pillai and McGarry^[46] studied clod bulk density, images of soil structure, and evaporation in samples from compacted wheel furrows. A distinct repair of soil structure was observed. Rapidity of restoration differed between crops and increased with the number of wet-dry cycles.

Soil tillage is technically difficult and costly in Vertisols, and several studies have been done of reduced tillage. Minimum, or zero, tillage and retention of stubble or fallow weeds show promise to improve soil structure, increase organic matter,^[47] and soil water storage,^[48] improve chemical fertility,^[49] optimize operation timeliness, and conserve water and soil in irrigated cotton.^[50]

The subsurface drainage systems in Vertisols have received much attention, often in connection with control of salinity and sodicity in irrigated agriculture.^[51–54]

Turpin et al.^[55] found that the combination of zero tillage and stubble retention increased the stability of soil aggregates and so increased the storage of rainfall during the fallow period. Minimum tillage in irrigated cotton produced a less dispersive soil with lower ESP and greater organic matter content in comparison with traditional plowing.^[56] McGarry, Bridge, and Radford^[57] found that no-tillage changes pore-size distribution and specifically increased the amount of continuous soil pores and counts of earthworms and termites in the upper 24 cm of soil. They related the higher hydraulic conductivity and infiltration in the no-tillage trials to this higher faunal activity.

Water Management

In the arid to semiarid areas, rain-fed cropping is strongly dependent on an efficient use of rain water. Water management in these regions must aim at maximizing transpiration and minimizing evaporation, runoff, and drainage.^[58]

In the subhumid and semiarid regions after heavy rainfall, excess water on flat terrain may cause flooding and prevent timeliness in seedbed preparations. On sloping terrain, runoff (often accompanied by soil erosion) is a danger.^[59]

Artificial internal drainage is generally not an option because of the low hydraulic activity and the internal soil movements (churning or pedoturbation) that will disrupt mole drains and break tile drains. However, successful mole and tile draining has been reported.^[45,60,61] Subsurface trenches were effective in yield increase.^[62]

Efficient use of irrigation waters requires data on plant available and readily available water.^[36] Water use regulation, or budgeting, in irrigation schemes can only be approximate: the very low hydraulic conductivity and the absence of a horizontal wetting front make the calculation

of the necessary volumes of water and timing of irrigations difficult.^[27] The final moisture addition at any specific depth approximates the original cross section of the cracks at that depth.^[32] This controls the amount of water taken by the soil at each watering and has been referred to as the “self-regulating” characteristic of the clay.

Rice cultivation under flood irrigation requires specific soil and nutrient management.^[63] Puddled fields give a higher yield than unpuddled fields, but puddling has a negative effect on the soil physical condition.^[64]

Soil Erosion

Vertisol surface soils are usually well aggregated, or there is a surface crust. Wind erosion of the dry surface soil is, therefore, unlikely. However, under extreme conditions, wind erosion does occur. Harris^[45] mentions wind erosion in southeastern Texas in Vertisols with calcareous surface soils tending to aggregate into sand-sized particles. Mermut, Patterson, and McDaniel^[4] report wind erosion from cold Vertisols in the United States and Canada. The surface granulation of soil is probably encouraged by freeze/thaw cycles in addition to drying and wetting.

Yule and Willcocks^[27] considered water erosion as the main limitation to sustain the production from Vertisols worldwide. Water erosion occurs on slopes as small as 1%. Some of the factors that make Vertisols highly susceptible to water erosion are as follows:

Much of the sediment erodes as aggregated material that has a lower bulk density than particles of a dispersed soil.

Wet Vertisols have low infiltration rates causing high energy runoff and soil particle removal and transport.^[65]

Crop or fallow weed cover, loose stubble, and roughing by harrowing help control soil erosion by water.^[66]

Slopes may also be reduced in length and percentage by the layout of graded, free-draining furrows, and thus disposing of runoff at non-eroding velocities.

Gilgai

Gilgai is a repetitive pattern of small mounds and depressions found in many Vertisols. In India and Sudan, it is restricted to the higher-rainfall regions.^[67,21] There are various forms of gilgai microrelief.^[68,69] Marked differences exist in morphological, chemical, and physical properties of soils associated with mounds and depressions and with intervening soils between them.^[70] With repeated leveling, the microrelief will eventually disappear. However, the soil profile differences in a gilgai complex (the area with a specific type of gilgai) are permanent features that continue to affect the growth of plants.^[68] Uneven growth is likely to be a consequence.

LAND USE SYSTEMS

Rain-Grown Annual Crops

The specific properties of Vertisols have prompted cultivators to devise appropriate practices. Harris^[45] considers timing of operations and water management the most important keys to successful production systems. In Australia, erosion control was the major innovation in the last several decades.^[27] Much of the cultivated land is contoured. Residue retention and reduced tillage have become standard practices.

A commonly used land layout is a system of alternating small ridges and furrows, or cambered beds separated by larger furrows (Fig. 3). The furrows not only collect rainwater but also serve as small irrigation ditches and surface drains. Examples are given by Ahmad.^[6]

In traditional cultivation, the deep Vertisols in India are fallowed during the rainy season and cropped on stored soil moisture in the post-rainy season. Weeds are controlled by tillage during the fallow period. Runoff and erosion may cause high water and soil losses. Toward the end of the rainy season, the land is prepared for planting.^[5]

A cultivation system with broad bed and furrows has the advantage over flat cultivation that it has a higher percentage of transmittent pores, as was found by Jayasree and Rao^[71] in Vertisols of India.

In the broadbed-and-furrow (BBF) system, developed at International Crops Research Institute for the Semi-Arid Tropics, Hyderabad, India, there is a rainy season crop and a post-rainy season crop.^[72,73] A cropping calendar is developed from a detailed study of the rainfall data over the years. Commonly, an early start of the rainy season crop allows a second crop, often by means of intercropping, using residual moisture. The land is laid out in semipermanent-graded BBFs on gradual slopes (usually

Fig. 3 Typical land layout for the cultivation of vegetable and small root crops. The beds are 3–4 m wide, and the drains serve for drainage or irrigation as needed.

Source: From Ahmad.^[6]

0.4–0.8%).^[74] Beds are slightly raised, acting as “mini-bunds” for moisture conservation and erosion control. The furrow is shallow but provides good surface drainage to prevent water logging of the crops growing on the bed. Excess water is drained through a system of field drains and grassed waterways. The excess water is collected in ponds and is used for complimentary irrigation of lower-lying fields.

Opportunity cropping refers to planting a crop whenever surface moisture conditions are satisfactory for seedling emergence, provided the soil moisture store equals or exceeds some specified fraction of PAWC. Carroll et al.^[50] showed that opportunity cropping, in combination with zero or reduced tillage to control episodic soil erosion, was the most appropriate system to manage the variable rainfall in Central Queensland, Australia.

Irrigated Crops

In Australia, Sudan, and other countries, cotton and several other annual crops are grown under irrigation. Fields are often laid out as cambered beds for crops alternating with furrows for flood irrigation. Irrigation gives full control of the cropping calendar and the water management in the dry season.

The quality of irrigation water is of particular importance in Vertisols. Soluble salts are not easily leached to deeper layers, and thus sodicity and salinity can develop. The Sudan Gezira irrigation scheme owes its success to high-quality irrigation water from the Blue Nile.

The watercourses and embankments of irrigation schemes are vulnerable to slumping and cracking. However, unlined irrigation canals and channels function well in the impermeable Gezira clays, provided the embankments are kept moist most of the time.

Pasture

Worldwide, most Vertisols are used for extensive rearing of livestock. The full productive potential of the soils is not realized in this land use system.^[6] The unavailability of forage, the water shortage in the dry season, and the inaccessibility during the rainy season are serious constraints for the exploitation of land, even in this non-intensive way. Overgrazing, sometimes triggering soil erosion, can be a problem near settlements. Livestock grazing caused the deterioration of soil physical properties in Ethiopian highland Vertisols.^[75]

Forestry and Agroforestry

The shortage of timber and fuelwood in many traditional farming areas on Vertisols has received increasing attention in the last decades. Shrubs and trees, which provide a crop or forage as well as wood, have been introduced in agroforestry systems. Larger woodlands have been established

with *Acacia*, *Eucalyptus*, *Casuarina*, and other species in Africa and Australia. Teak forests (*Tectona grandis*) are successful in higher-rainfall areas in Trinidad^[6] and Indonesia. An *Eucalyptus globulus*-based agroforestry system appeared to be the best option to cultivate seasonally waterlogged highland Vertisols in Ethiopia.^[76] Young^[77] gives an outline of agroforestry practices that can be effective in the control of erosion and maintenance of soil fertility.

GEOTECHNICAL PROBLEMS

Buildings and roads built on Vertisols need special precautions against the effects of swell–shrink cycles and the associated movements of the soil. Walls of houses crack and roads of any kind become uneven and intractable. Fredlund^[78] discusses the geotechnical problems in urban land use on Vertisols.

CONCLUSION

Vertisols are clay soils in which the clay fraction is dominated by swelling clay minerals, mainly smectites. Vertisol formation is favored by a warm climate with alternating wet and dry seasons. Vertisols have a characteristic morphology resulting from the swelling and shrinking of the clays upon changes in moisture content. Soil properties have a distinct impact on agricultural practice. The soils are used for rain-grown and irrigated cropping. They require specific agronomic techniques and land use systems. Minimum or zero tillage has a positive effect on soil structure and soil/water relations.

Abstract

High smectite clay causes the formation of cracks that are a striking feature of black Vertisols, which are also distinguished by the presence of potholes. Soil cracks improve water recharge through preferential flow during the rainy season. A network of surface and subsurface cracks is also a prerequisite to the formation of a pothole. Cracks also extend the soil–air interface in the soil profile. Thus, the evaporation loss is high from surface and subsurface cracks, which also increase the number of wetting/drying cycles. Loss of soil moisture in rainfed regions can severely jeopardize crop productivity. Thus, there exists a strong need to understand the cracking patterns in Vertisols for the management of cracks and to minimize loss of profile soil moisture. Cracking patterns can be altered by management practices such as tillage, addition of soil amendments, and different crop covers/cropping systems. Despite their importance, scientific knowledge on managing surface cracks in Vertisols is very scanty. Different management practices, namely conservation tillage, residue retention, and addition of soil amendments, were effective in reducing crack formation in Vertisols. This entry lucidly revolves around the surface cracks and its management in Vertisols.

INTRODUCTION

The world's soil resource has been broadly classified into 12 distinct soil orders. Out of these, Vertisols (Latin *verto*, “turn”), which cover ~2.4% of global ice-free land areas, are uniquely characterized with a high content of shrinking–swelling clay, dark colored, and prominent surface cracking varying with moisture contents. Cracks are the unique feature of Vertisols and are used as one of the criteria in defining Vertisols in Soil Taxonomy.^[1] When Vertisols dry, mainly the following four shrinkage phases are possible: structural shrinkage, basic or normal shrinkage, residual shrinkage, and zero shrinkage leading to the formation of cracks. Basic shrinkage, traditionally referred to as normal shrinkage, accounts for most of the shrinkage in agricultural soils, generally between soil water potentials of -33 to < -1500 kPa.^[2] In this shrinkage phase, water is lost from the interclay domains causing shrinkage to be equidimensional resulting in crack formation. The soil blocks between the cracks contain all the structural and residual porosities, whereas the cracks (including the cracks above the soil surface) contain only the basic or normal shrinkage porosity.^[3]

DIFFERENT TYPES OF CRACKS IN VERTISOLS

Grossman et al.^[4] have grouped cracks in Vertisols into the following three sets:

1. Vertically oriented cracks that outline large blocks or prisms at the upper part of the soil. The cracks are wide, about 5–10 mm, and become progressively deeper as the soil dries out.
2. Cracks that form angular or blocky elements at the soil surface. These form at high water tensions, perhaps close to the wilting point.
3. Cracks that form deeper in the soil and are related to the internal pedoturbation associated with the slickensides.

The first two sets of cracks exhibit properties that are important in land use and management. Vertisols with a granular surface soil mulch (the first set) tend to have lower bulk densities, perhaps due to a slightly higher organic matter content and to the space between the granules. Soils with angular surface structure (the second set) are easier to till, and roots can permeate the spaces and move deeper. In addition, the filled crack spaces are probably the most

Fig. 1 Surface black soil showing (A and B) intersecting cracks and (C and D) potholes.

likely areas for roots to establish during the next season because water flows easily through these areas.

Cracks have several direct as well as indirect effects on crop performance. Because the rhizosphere is dehydrated last, the cracks normally form away from the stubble of the previous crop that locates at the center of the polygon. In this case, dislodging of the plant is not a problem, but when the rhizosphere also dries out, soil shrinkage could strangle or shred crop roots. Cracks also retard surface wetting from any off-season rains. At the beginning of the rainy season, much of the water is not available to the plants because the water is rapidly evacuated by the void system. During the initial rain showers, the subsoil below the zone of the cracks is moistened. Successive rains moisten the top few centimeters of the soil, causing it to swell and seal the surface. Subsequent rains cause ponding, making tillage difficult, and facilitate faster soil erosion.^[5] Soil cracks may improve water recharge through preferential flow during the rainy season. A network of surface and subsurface cracks (Fig. 1A and B) also leads to pothole formation (Fig. 1C and D). The size of the cracks gets larger when two or more such cracks meet. Consequently, the runoff drains into these cracks, where a deep and wide hole is formed during the rainy season. Such holes are locally known as potholes or pipe holes. In this process, the top soil at the edge of the

cracks gets slumped down into the crack, resulting in the formation of potholes. Through subsurface cracks/channels, the eroding soil may join somewhere with the adjoining ravine systems posing a serious problem of gully head extension that results in the loss of arable land and crop productivity.^[6] Cracks also extend the soil–air interface in the soil profile. Consequently, the evaporation loss is high from surface and subsurface cracks, which also increases the number of wetting/drying cycles. Loss of soil water in rainfed regions can severely jeopardize crop productivity. Thus, the management of cracks in Vertisols is inevitable for sustainable productivity in these areas.

MANAGEMENT OF SURFACE CRACKS

Different agronomic practices such as tillage systems and nutrient management indirectly affect the cracks formation, by directly affecting soil water content and soil organic matter. In India, a systematic survey was conducted on cracks/pothole dimensions (length, width, and depth) under various land conservation treatments, namely contour furrows (CFs), conservation bench terraces (CBTs), residue (wheat straw) incorporation (RI), control (without conservation measures), during dry spells after the onset of the monsoon under various field treatments.^[7] The greater volume of potholes was observed in uncultivated fields than in cultivated ones (Table 1). It was due to the unbroken, gentle slopes that allowed silt-laden runoff to travel longer distances before entering cracks to form potholes. The data further reveal that among the cultivated fields, the control field had the greatest volume of potholes followed by CBT, RI, and CF. The CBT treatment had a large volume of potholes that is attributed to gentle terrace slopes (1%), which results in greater runoff into the cracks and leads to more pothole formation. In the RI treatment, the volume of potholes was less than that of the CBT, and this is as a result of better soil aggregation and porosity, which offer better protection against sudden slumping or erosion into potholes. The lower volume of potholes in the CF treatment is explained by the higher water content in the profile because of greater absorption of rainfall across the field. This shows that conservation measures are very effective in

Table 1 Pothole dimensions under different treatments in Vertisols (Typic Chromustert).

S. No.	Treatments	Length (m)	Width (m)	Depth (m)	Volume (m ³ ha ⁻¹)
I	Cultivated field				
	CF	0.24 ± 0.04 (34.22)	0.20 ± 0.02 (22.36)	0.17 ± 0.02 (25.14)	119.7
	CBTs	0.18 ± 0.02 (22.70)	0.19 ± 0.02 (24.97)	0.46 ± 0.04 (20.91)	231.8
	Residue incorporated	0.29 ± 0.03 (21.03)	0.17 ± 0.02 (17.32)	0.22 ± 0.03 (22.77)	142.8
	Control (cultivated)	0.32 ± 0.03 (19.60)	0.27 ± 0.05 (20.10)	0.39 ± 0.06 (28.61)	450.1
II	Uncultivated field	0.58 ± 0.05 (18.89)	0.41 ± 0.06 (32.72)	0.31 ± 0.09 (62.59)	573.3

reducing crack/pothole formation in the black soils of southeastern Rajasthan, India. It is also possible that cultivated fields had a smaller volume of potholes than uncultivated fields because of regular ploughing that mixed accumulated clay in the lower subsoil. In uncultivated fields, a higher amount of clay accumulates that could have resulted in a greater occurrence of potholes.

Nevertheless, potholes and cracks are omnipresent in these black Vertisols. The application of manures and amendments such as crop residues helps to minimize cracks by promoting soil aggregation. The creation of surface dust mulch also reduces cracks, which helps successful crop growth. Tillage and crop rotation directly affect soil structure. Thus, the selection of appropriate tillage practices is imperative for these black soils to minimize the occurrence of soil cracks. Clay accumulates where cracks intersect (slickensides) and also accumulates in the subsurface soil at 60–70 cm. Enormous pressure is developed as a result of swelling (when wet) and shrinking with wide cracks formed during the dry season. Ploughing immediately after the harvest during the postrainy season helps to prevent weeds from producing seeds, exposes hibernating insects and disease-causing organisms, improves soil fertility, fills cracks, and pulverizes the soil, thereby improving moisture retention. Intercropping of cereals and pulses such as in the sorghum/pigeon pea system is effective in controlling crack

formation because of the contrasting root patterns, which aids aggregate formation and the breakdown of the subsurface hardpan. Selection of short-duration crops that complete their dough stage (grain filling stage) before crack development is another option to minimize the problem. *In situ* moisture conservation practices, such as construction of contoured or graded bunds, also help reduce crack formation due to changes in the moisture regime.

Worldwide, several studies came into conclusion that conservation agricultural practices such as no-tillage, reduced tillage, and residue retention on surface, helps in increasing profile moisture and soil organic carbon. High soil carbon facilitates soil aggregation and improves micro-environment for soil microorganism and macroporosity, which resulted in high soil profile moisture and reduces possibilities of crack formation under conservation agriculture practices compared to traditional practices. In contrast, higher crack volume is found in no-tillage system compared to conventional tillage system (Fig. 2A).^[8] Observations were recorded under soybean–wheat cropping system in month of November after 2 years of imposition of tillage treatments. Possibilities of higher crack volume in no-tillage system were due to no residue generation in soybean crop, which left soil bare to evaporation. However, in another study, lower volume of cracks was observed in no-tillage compared to conventional tillage system.^[9]

Among different nutrient management practices, results indicated that the least cracks in 100% nitrogen, phosphorus, and potassium (NPK) + farm yard manure (FYM) at 4 t ha^{-1} . The effects of nutrients on crack volume may be attributed to the fact that NPK + FYM registered significantly greater root development than other nutrients treatments.^[8] The root produced might have reduced the shrinkage process by anchoring the soil mass.^[10] Crack volume was also recorded under different crop covers after two crop cycles (Table 2), which revealed that higher crack volume was registered under cultivated fallow.^[11]

In soil science, amendments are frequently used to reclaim soil; to improve soil physical, chemical, and biological health; and to promote plant growth and vigor. A soil amendment can be any material added to a soil with an aim to provide a better environment for plant roots. Commonly used amendments in area of soil science are the residual materials or by-products from other processes and include municipal biosolids, manures, litters, wood ash or saw dust, coal combustion products, neutralizing lime products, compost, and traditional agricultural fertilizers. Of these, five soil amendments, namely wheat straw (S1), FYM (S2), sawdust (S3), gypsum (S4), and fly ash (S5), with a control (S0) were selected to conduct a preliminary study at Indian Council of Agricultural Research-Indian

Institute of Soil and Water Conservation (formerly ICAR-CSWCRTI), India, on crack occurrences.^[12] Amendments were mixed into the soils at the rate of 0, 2.5, 5.0, and 10 g kg^{-1} and kept in plastic trays (Fig. 3). These trays were kept in shade without any disturbances for monitoring the crack development. It was evident from the study that the addition of soil amendments was very effective in reducing the crack formation/volume. Irrespective of the soil amendments, increased rate of application of soil amendments had significant effect on reduction of crack volume (Fig. 4). Among various amendments studied, wheat straw recorded the lowest crack volume followed by FYM, sawdust, gypsum, and fly ash.^[12]

Similarly, soil moisture content also recorded higher value under wheat residue amended soil at 10 g kg^{-1} of soil compared to other treatments and control. Data on percent decrease of crack volume in amendments added at 2.5 g kg^{-1} of soil over control have revealed that the highest reduction (-74%) was observed under wheat straw, and the lowest reduction (-23%) was registered under fly ash. Beneficial effect of residue addition on the reduction of crack parameters was also reported.^[13,14] As the dose of amendments increased (i.e., from 2.5 to 10 g kg^{-1} of soil), the percent reduction was also greatly increased. Results indicated that the addition of soil amendments results in reduction of crack volume. Based on the results obtained, a follow-up research was carried out on experimental farm, and the result indicated that all amendments reduced crack volume in cropped and fallow plots during winter (Table 3). Wheat straw being most effective during winter months, however, no effect of amendments was observed during summer. Use of amendments improved crop yields. Among different soil amendments studied, wheat straw was most effective in improving grain (40%) and biomass yields (33%). Cost-benefit analysis showed that FYM and fly ash were the only remunerative options, which increased returns by 123% and 43%, respectively. Use of amendments was not economical for grass production; however, fly ash may be recommended, if cracking behavior of soils is required to be managed.

CONCLUSIONS

Cracking is a striking phenomenon of Vertisol and has several positive and negative effects on agricultural soils. The positive effects of cracks include improved drainage, improved infiltration, and improved soil structure, whereas the negative effect of cracking is the rapid transport of water with solutes through soil cracks, which often leads

to crop water and nutrient stress and sometimes leads to groundwater contamination. Therefore, suitable land use with good soil management practices such as adopting conservation tillage, leaving crop residue on soil surface, using different soil amendments, and selecting appropriate crops in the crop cycle would be the best option to reduce the formation of wide cracks. Moreover, it also helps in preventing loss of fertile topsoil through potholes during the

Table 3 Effect of soil amendments application on crack volume under different land uses.

Vesicular Crusts

Patrick Drohan

Department of Crop and Soil Sciences, Pennsylvania State University, University Park, Pennsylvania, U.S.A.

Abstract

The vesicular horizon is a surface, or near surface, soil horizon composed of tiny non-connected circular, ovoid, or prolate pores commonly called vesicles. The horizon has been found to form in soils of a variety of parent materials deposited via eolian processes as dust and is often composed of fine textures. Vesicle pore formation is hypothesized to occur by several different processes with the most widely accepted being entrapped air and soil particle movement following soil wetting (air entrapment due to a wetting front from rain or snowmelt). Field vesicular porosity has been noted to occur within platy and columnar structure. While fragile and easily disturbed by most fauna and humans, vesicular horizons have been noted to persist in environments where surface stability is greatest; increasing surface stability can be due to crusts, pavements, or landscape age. The vesicular horizon has been hypothesized to restrict plant growth with one possible mechanism being that non-interconnected pores found in the horizon may restrict water movement through the horizon, especially in thicker horizons. Field research on hydraulic properties of vesicular horizons has noted significantly lower hydraulic conductivities in vesicular horizons on surfaces of increasing geomorphic age because of greater accumulations of clay. Owing to its effect on water movement into arid soils, the vesicular horizon may be the most influential soil horizon in arid landscape geomorphology and pedogenesis.

INTRODUCTION

The vesicular horizon is a surface, or near surface, soil horizon composed of tiny non-connected circular, ovoid, or prolate pores commonly called vesicles.^[1–4] In some cases, a thin (1 mm to 5 cm; Fig. 1A) horizon or silt cap may over the horizon.^[5] The vesicular horizon is found in arid environments^[1,3,6,7] and can form in association with mineral crusts, biological crusts, and stone pavements. As dating of the vesicular horizon has proved to be difficult, soil ages are believed to range from the Holocene to the Pleistocene.^[1,5,8] Vesicles in the horizon are typically less than 1 mm in diameter,^[3,7] however, in the Canadian High Arctic, vesicles up to 30 mm in diameter have been observed.^[7] The shape of vesicles can be quite variable and may be influenced by soil drainage and surface stability.^[7] Bunting^[7] hypothesizes that irregular drying, or the diffusion of air or water under pressure, may contribute to irregularly shaped vesicles.

FORMATION

Vesicle pore formation is hypothesized to occur by several different processes: 1) entrapped air and soil particle movement following soil wetting (entrapment due to a wetting front from rain or snowmelt),^[1,7] 2) heated air,^[3] 3) release of carbon dioxide via drying of carbonate soils and solution

(Paletskaya et al., 1958, as cited in Evenari et al.^[3]); and 4) ice crystal formation and melting. Several researchers have demonstrated vesicle formation in the laboratory using sieved soil from the field that originally had vesicles.^[1,3,7] Soil particle movement not only plays an important role in vesicle formation but also in the movement of rock fragments to the soil surface, which is believed to be one mechanism explaining arid lands pavement formation.^[1] Field research has confirmed this laboratory result.^[9]

Vesicular porosity has been noted to occur under irrigation furrows,^[2] in cracks and fissures of Lithosols in the southern Sinai,^[3] in tropical environments as a fossil feature where laterite soils are present,^[10] in termite mounds (Lee and Wood, 1977, as cited in Bunting^[7]), and in humid soils where earthworms are present.^[7]

STRUCTURE

Field vesicular porosity has been noted to occur within platy^[1,11] and columnar structure.^[5,8,9] Vesicular porosity has been found to quickly reform in the laboratory following disturbance^[1–3] and to more closely resemble *in situ* vesicular porosity with numerous laboratory wetting and drying cycles; repeated wetting and drying decreases the number of pores but increases the total porosity.^[12] While field vesicle shape is often ovoid, less rounded shapes have been observed with laboratory rewetting experiments.^[12]

Laboratory experiments have shown that pores near the soil surface undergo microerosion and microdeposition owing to percolation.^[12] Coatings of non-laminated and fine-textured particles,^[12] clays,^[5] and calcite^[3] have been observed on vesicle surfaces. Plate-like silt and clay particle vesicles with a pavement-like appearance^[5,13] and layers of differing thicknesses have also been observed within vesicles.^[13]

STABILITY

While fragile and easily disturbed by most fauna and humans, vesicular horizons have been noted to persist in environments where surface stability is greatest; increasing surface stability can be due to crusts, pavements,^[3] or landscape age.^[14] Vesicle stability over time has also been attributed to cementation by calcium carbonate^[3] and

possibly to rapid dewatering of the horizon. Evenari et al.^[3] and McFadden et al.^[5] suggest that the formation of silt and clay coatings interior to vesicles can increase vesicle stability. However, if unprotected by a crust or pavement, the vesicular porosity is prone to destruction. On the basis of laboratory experiments, Springer^[1] hypothesized that vesicular porosity was unstable itself in which soil with vesicles was repeatedly wetted, resulting in vesicle destruction and soil rearrangement.

PHYSICAL, CHEMICAL, AND MINERALOGICAL PROPERTIES

The physical, chemical, and mineralogical properties of the vesicular horizon distinguish it from other soil horizons and help explain its genesis and ecosystem role. The thickness of the horizon may range from a few millimeters to several

centimeters,^[3] and soil bulk densities of the horizon range from 0.9 to 1.52 g cm⁻³.^[1,2] The horizon has been found to be formed in soils of a variety of parent materials deposited via eolian processes^[1,5] as dust and is often composed of a wide range of soil textures (fine sand, silt, silt loam, and clayey silt),^[3,7] very fine sandy loam,^[1] and sandy loam.^[5] In the laboratory, coarse sand has been observed to produce vesicular porosity.^[3] The vesicular horizon has been observed to contain few, if any, stones.^[7-9]

From a literature survey, McFadden et al.^[5] report vesicular horizon soil pH to be between 7.0 and 8.9 and conductivity to be 0.1–0.5 mS cm⁻¹. Mineralogy consists of quartz dominantly in the coarse fraction; with finer fractions having a very fine silt, micritic calcite, and unoriented silicate clay.^[5] Clay-size mineralogy consists of a mixed assortment of mixed-layer clay minerals, smectite, kaolinite, illite, quartz, and rare occurrences of palygorskite (McFadden, 1982; McFadden et al., 1986; Reheis et al., 1995, as cited in McFadden et al.^[5]). In soils from Patagonia, an exchangeable sodium percentage >15 was important in vesicle formation.^[15] Soil color varies depending on geographic location where formed and whether one is interior or exterior of a ped.^[9] In arid landscapes, vesicular horizon colors are typically lighter due to less organic matter.^[5]

HYDRAULIC PROPERTIES

The vesicular horizon has been hypothesized to restrict plant growth^[8] with one possible mechanism being the non-interconnected pores found in the horizon,^[12] which may restrict water movement especially in thicker horizons. Field research on the hydraulic properties of vesicular horizons has noted significantly lower hydraulic conductivities in vesicular horizons on surfaces of increasing geomorphic age due to greater accumulations of clay. Surface age has been shown in the Mohave Desert, U.S.A., to be a good predictor of vesicular horizon-saturated hydraulic conductivity.^[8]

CONCLUSION

Owing to the nature of the vesicular horizon's non-interconnected pores restricting water movement through the horizon, many researchers have speculated that the vesicular horizon could be the most influential soil horizon in arid landscape geomorphology and pedogenesis. From an ecological standpoint, the horizon likely plays a significant role in arid ecosystems, and further research should address the spatial extent of such horizons in various arid landscapes and its role in controlling water and nutrient movement into the soil. From a human health perspective, vesicular horizons once disturbed may pose a human health

risk because of atmospheric dispersion of fine particles that can contribute to respiratory distress. Further research should explore the horizon's disturbance in proximity to urban development and human health consequences and its resilience to disturbance.

Abstract

It has been recognized that bamboos growing in the wild play an important role in soil nutrient buildup and maintenance of soil fertility. However, the cultivated one that has been managed by farmers in Asia over millennia for their livelihood was little studied with respect to its role in soil nutrient status. Therefore, the specific aim of this entry is to describe the usefulness of bamboo plantations to improve soil quality and sustain agronomic productivity. Field measurement of soil properties indicates soil bulk density decreases with an increase in age of bamboo plantation from 1.42 Mg m⁻³ under 2-year-old plantations to 1.27 Mg m⁻³ under 20-yr-old plantations with an overall decline of 11% in soil compactness. On the contrary, there is an increase in water holding capacity (30.3–41.5%), and of the concentration of soil organic carbon (SOC; 0.68–1.17%), total nitrogen (0.11–0.28%), available phosphorus (1.73–4.53 mg 100 g⁻¹), and exchangeable potassium (0.20–0.67 cmol (+) kg⁻¹) with an increase in plantation age by 37, 72, 155, 162, and 235%, respectively, from soil under 2–20-year-old plantation. The SOC stock and sequestration rate of village bamboo plantation to 10 cm depth range from 9.66 to 14.86 Mg ha⁻¹ and 0.14 to 0.39 Mg ha⁻¹ yr⁻¹, respectively. The increasing trend of nutrient and SOC stock suggests the potential of village bamboo management in restoring soil quality through onsite enrichment, conservation, and cycling of carbon and nutrients.

INTRODUCTION

Bamboo, the giant grass, is a vernacular term for members of the subfamily Bambusoideae of the family Poaceae. In Asia, the history of bamboo is inextricably interwoven with human history so much that parts of Asia could be described as a “bamboo civilization.” Bamboo has unique rhizomal growth feature by which culms (individual bamboo) in the clump (cluster of culms) are interconnected and reproduce asexually to produce new culms every year. This characteristic distinguishes bamboo from most other woody plants. Based on the bamboo production area, for example, rural landscape or forest areas can be termed as “village bamboos” or “forest bamboos.”^[1] In contrast with forest bamboos, village bamboos are cultivated and managed in a traditional homegardening system (an age old tropical agroforestry system) to fulfill diverse livelihood requirements and provide numerous environmental services to rural communities. Furthermore, village bamboos protect traditional homesteads from winds, provide construction materials and fuel wood.

Bamboo plays an important role in maintaining and improving the nutrient status of the soil.^[2] From a comparative study, it was reported that the presence of bamboo in

the forest significantly affected the physical and chemical properties of soil.^[3] Nutrient content in soil was positively related to yield and explained much of the variation in yield across bamboo sites and regions in China.^[4–6] Hence, bamboo growth and biomass are positively related to soil organic matter, which is the primary source of nutrients in bamboo cultivation sites in Korea.^[7,8] Bamboo can grow in relatively poor soil and efficiently make use of the available nutrients and build up relatively fertile soil around the clumps.^[9] While studying the relationship between soil conditions and fountain bamboo (*Sinarundinaria fangiana*), it was observed that bamboo grew well on acid soil with low base saturation, deep, and low gravel content of soils but died in the alkaline, shallow, calcareous soil with high gravel content.^[10] A canonical correlation analysis for bamboo growth showed that surface soil depth, total nitrogen (N), and soil organic matter content had high positive correlation, and clay content and cation exchange capacity were negatively correlated with the bamboo growth.^[8] Studies related to soil and bamboo revealed emphasis has been given to forest bamboos, whereas village bamboos remain unexplored although it forms an important component of the agroforestry systems of south Asia, especially in India and Bangladesh. In traditional

agroforestry systems, bamboos are grown on soils of poor quality or degraded site of the holdings. Therefore, bamboo has been traditionally used to reclaim degraded lands. Despite the significant impact of village bamboos to the livelihood and wellbeing of farmers, there exists the need of scientific understanding of the role of traditional village bamboo management on sustaining soil nutrient status. Therefore, this entry is to understand how village bamboo plantations impact soil quality.

Traditional Village Bamboo Management System

In village landscapes, bamboo plantation (Fig. 1) is the inherent social and ecological attribute of local farming practices. For optimum utilization of traditional homegardens, farmers have divided it into different landforms depending on the suitability of the species for different soil quality. Each land form varies by certain environmental factors and specific vegetation types. Traditional management system for plantation development is outlined in Fig. 2. Under the traditional management system, propagation is practiced through offset (belowground vegetative

Fig. 1 Village bamboo plantations in NEI.

Fig. 2 Traditional management system for raising bamboo plantation.

part). Offset from 1- to 2-year-old culms is cut at about 1.5–2.0 m height, excavated along with a portion of rhizome, and planted during the rainy season. Bamboo plantation management fulfills both subsistence and commercial needs of the bamboo growers and generates employment at the community level (Fig. 3). Due to its site specificity in the homegarden, bamboo builds up a complex interplay between soil and vegetation implying the prevalence of a different microclimate under bamboo canopy than that under other parts of the homegarden.

SOIL PROPERTIES AND BAMBOOS

Data from North East India (NEI) on soil physical and chemical properties with respect to age chronosequences (2-, 5-, 10-, 15-, and 20-year-old clumps) of bamboo plantation (*Bambusa cacharensis*) are presented in Fig. 4. Soil bulk density (BD) decreases with increase in clump age, and all parameters exhibit a strong negative correlation with the age (Fig. 4). Such a decreasing pattern is attributed to the increasing amount of soil organic carbon (SOC) from input of litter fall and root biomass with increase in clump age. A significant effect of bamboo species (*Guadua angustifolia*) on BD and SOC concentration has also been reported in soils of montane region of Ecuador.^[11] A similar trend is also reported for *Dendrocalamus strictus* from some coal mined areas in Central India^[9] and Moso bamboo (*Phyllostachys pubescens*) of Japan.^[12] The number of culms per clump increases with the increase in clump ages^[3] which increases the litter fall under aged clumps.^[13]

Increase in clump age accumulates more SOC from litter mass that subsequently influences soil water holding capacity ($R^2 = 0.99$, $P < 0.001$). There exists a statistically significant correlation of SOC content with clump age ($R^2 = 0.95$, $P < 0.001$; Fig. 4). The SOC is an important determinant of soil quality, especially of nutrient reserves and soil fertility.^[14] Bamboo growth and biomass are

Fig. 3 Diversity in utilization of village bamboos.

positively correlated with SOC content because it is a primary source of nutrients in bamboo cultivation.^[9,15] Total N content also increases with increase in clump age. A similar trend is observed for *D. strictus* plantations in Central India.^[9] Increase in N content is strongly correlated with the SOC content ($R^2 = 0.98$, $P < 0.001$) of the bamboo plantation. Slow rate of bamboo litter decomposition and subsequent nutrient release replenish soil carbon (C) and N stocks and positively influence the soil microenvironment^[16,17] and, therefore, signify the role of bamboo litter in enhancing C and N contents under its canopy. Concentration of available phosphorus (P) and exchangeable potassium (K^+) increases with increase in clump age, and these variables are strongly correlated (Fig. 4). The bamboo stand (*P. pubescens*) mixed with other trees has high productivity and strong nutrient recycling ability,^[18] indicating the importance of bamboo agroforestry in enhancing P and K^+ contents in soil. Increase in the concentration of P and K^+ under managed bamboo plantation (*Phyllostachys praecox*) has also been reported in China.^[19] Further, SOC concentration is positively correlated with that of P ($R^2 = 0.95$, $P < 0.001$) and K^+ ($R^2 = 0.92$, $P < 0.001$) under bamboo canopy. For a bamboo forest in the NEI, over harvesting of bamboo culms for commercial purposes impoverishes the soil nutrient status^[20] and thus reduces soil fertility. Bamboo culms are harvested selectively under bamboo agroforestry system.^[13,21] This strategy develops a balance between harvest and production for maintaining a steady stock, which subsequently increases litter deposition over time, enhancing SOC and, therefore, P and K^+ contents in soil.

SOC Stock and Sequestration Rate

In bamboo forests, the SOC stock is about twice as much as in the aboveground vegetation.^[22] The SOC stock (up to 10 cm soil depth) under bamboo in NEI ranges from 9.7 Mg ha⁻¹ under 2-year-old plantations to 14.9 Mg ha⁻¹ under 20-yr-old plantations and increases linearly with increase in age ($R^2 = 0.94$, $P < 0.05$). In Moso bamboo plantation, the average SOC stock of 94 Mg ha⁻¹ up to 1 m depth has been reported from China.^[23] In montane region of Ecuador, SOC stock of *Guadua* bamboo forest is as much as 52–96 Mg ha⁻¹ up to 30 cm soil depth.^[11] The SOC stock ranges from 25 to 35 Mg ha⁻¹ up to 30 cm soil depth in a managed bamboo (*P. pubescens*) in Zhejiang Province, China.^[23] Soil C stock ranges from 23.2 to 29.1 Mg C ha⁻¹ in a poplar (*Populus deltoides*)-based agroforestry systems in India.^[24] The SOC stock of 21.6–25.6 Mg C ha⁻¹ has been reported in soil under acacia (*Acacia nilotica*), white catechu (*Acacia polyacantha*), and mangium (*Acacia mangium*) agroforestry systems after 5 years of plantation establishment.^[25] The estimated SOC stock of bamboo plantation in NEI (10–15 Mg ha⁻¹, 10 cm depth) is comparable to those for other species in 0–10 cm depth, signifying the role of village bamboos in SOC stock management. The SOC sequestration rate (0–10 cm depth) in NEI varies with plantation age. The highest SOC sequestration rate is 0.39 Mg ha⁻¹ yr⁻¹ for 5–10-year-old plantation that gradually decreases to 0.14 Mg ha⁻¹ yr⁻¹ in 15–20-year-old plantation. This signifies saturation of SOC sink capacity with increase in the plantation age. However, this trend is based on a few sampling points from a few

Fig. 4 Correlation of bamboo plantation age with different soil parameters in bamboo agroforestry system in NEI.

bamboo clumps. Therefore, a well-designed study is needed to strengthen the data bank. A third-order polynomial equation ($Y = 0.0815X^2 + 0.5134X - 0.4081$, $R^2 = 0.95$, $P < 0.05$) best explains the SOC sequestration rate with respect to age chronosequences of a bamboo plantation. The SOC sequestration rate of $0.44 \text{ Mg C ha}^{-1} \text{ yr}^{-1}$ is reported from bamboo-based agroecosystems in upland of Vietnam.^[15] A study from China shows that SOC sequestration rate can increase up to $6.3 \text{ Mg C ha}^{-1} \text{ yr}^{-1}$ (up to 40 cm soil depth) in an intensively managed bamboo forest (*P. praecox*).^[26] Therefore, opportunities exist to enhance SOC sequestration rate in village bamboo stand by adopting scientific management systems.^[27]

CONCLUSION

An increasing trend in nutrient and SOC stock with increase in clump age under the bamboo canopy suggests

the potential of bamboo in soil restoration, onsite nutrient conservation, nutrient cycling, and C sequestration. Measured SOC stock and sequestration rate are comparable to those of other agroforestry and bamboo-based agroecosystems elsewhere for similar soil depths, suggesting the high potential of traditionally managed village bamboos in sustaining productivity and restoring soil quality. However, more research is needed to evaluate the management systems that can further promote SOC sequestration rate and improve soil quality under village bamboo plantations.

Waste Rock and Overburden Dumps: Rehabilitation

Martin V. Fey

R.D. O'Brien

A.J. Mills

Department of Soil Science, University of Stellenbosch, Matieland, South Africa

Abstract

Improved mining technology over the last few decades has resulted in an increasing trend toward open-cast methods, thereby leading to the disturbance of large areas of land to access the natural resources beneath the surface. This entry focuses on principles that would apply to the whole range of spoil materials—from those produced by conventional quarrying to those from strip mining of vast ore deposits over hundreds of square kilometers. The nature of the spoil may vary from relatively hard, coarse, unweathered rock fragments to fine, soft, easily erodible earthy materials. In all cases, the common thread is the need to first remove whatever soil cover exists before mining can commence. This soil cover may either have been lost or, at least if stockpiled for later use in rehabilitation work, severely disturbed through mixing of topsoil with deeper horizons and sterilized to some degree as a result of stockpiling. A wide variety of practices have been applied to restore landscapes that have been affected by mining. The focus of this entry will be on modern methods and recognized principles of rehabilitation.

DETERMINATION OF REHABILITATION GOALS BEFORE MINING COMMENCES

A prerequisite to mining should be the execution of a baseline survey that identifies and maps the existing soils and establishes the potential land use as a means of guiding the formulation of rehabilitation goals. While the planned rehabilitation program is unlikely to completely dictate mining methods, the greater the cooperation between the mine and rehabilitation planners, the better the chances of successful rehabilitation. Physical and chemical characterization of each overburden layer needs to be done prior to mine development. This will reveal the potential for compaction, erosion, and satisfaction of plant growth requirements in terms of water availability, nutrition, and toxicity problems. Soil scientists and mining engineers often disagree over what constitutes “topsoil;” the onus should be on the soil scientist to demonstrate the special character of true topsoil in terms of the contribution made by humus to soil structure, aeration, water holding capacity, plant nutrient supply, and toxicity buffering, and also in terms of microbiological activity. Topsoil may also constitute a seed bank that may be of enormous value during revegetation.

The final land use must be decided upon before the development of the mine and should consider factors such as stability and degree of permanence and not just the level of productivity to be achieved. The final land use will also influence the landscape design, fertilizer, liming, and maintenance requirements, and the cost of reclaiming the area. However, the final land use should be seen as the

minimum requirement for rehabilitation and not inhibit research to develop improved methods that could lead to a more stable end land use. The aim of landscaping of waste dumps is to produce slopes that are not prone to erosion and are compatible with the proposed land use and the surrounding landscape. Erosion of waste dumps can have severe effects on the success of the reclamation, leading to exposure of encapsulated waste rock, high sediment loads, and lower water quality in receiving streams. Various computer models have been developed to aid the design of waste dumps^[1] by predicting erosion and soil loss from waste rock dumps. These models range in complexity from short-term stability during the construction stage to topographic evolution models simulating erosion over centuries.

There is no typical design or shape of waste rock and overburden dumps. Economic circumstances often dictate, however, that the amount of landscaping be kept to a minimum, in which case there is still a considerable slope angle on the sides of the dump. This may have important implications for revegetation because of differential temperature and moisture regimes on north and south aspects and the need for special measures such as terracing to trap water and reduce erosion. The latter can in some cases be counterproductive because of the tendency of contour terraces to concentrate the flow of water and to become breached if rainfall is too intense. The consequences can then be quite devastating in the form of deep gully erosion. [Fig. 1](#) gives an example of the landscaping challenges presented by waste rock dumps.

Fig. 1 Waste rock overburden alongside open-cast coal mining on the South African highveld.

RESTORING A GROWING MEDIUM FOR PLANTS

There are physical, chemical, and biological factors that need to be considered in restoring the capacity of overburden materials to sustain plant growth.

One of the biggest physical problems is compaction arising from the use of machinery during overburden placement after mining. Some degree of soil compaction is inevitable as soils are stripped and stored for later use. It is generally agreed that soil handling has a marked effect on the success of any reclamation scheme. In an attempt to remove the effects of compaction on the replaced soil material, various forms of subsoiling or ripping using tines drawn by crawler tractors are used. These methods are not always successful, and alternative methods of soil placement may need to be developed. One such method, called loose tipping,^[2] involves the tipping of soil material from dump trucks, with the heaps being spread by an excavator operating from the overburden surface. With this method, there is no need for vehicles to travel over newly restored soil. In some cases, the heaps are left in place to serve as windbreaks, assist in recruitment of windblown seeds, and reduce both erosion and sandblasting effects on new vegetation in areas exposed to strong winds. Eventually, natural forces reduce the relief of the mounds.

Another serious physical problem is the tendency of many spoils to disperse readily under raindrop impact, developing a surface crust that inhibits seed germination and seedling emergence and reducing the infiltration of water and diffusion of oxygen into underlying layers. Severe erosion can result from crust formation. Organic or gravel mulches, or aggregate-promoting chemicals applied on the surface, such as gypsum or polyacrylamide, are variously employed in such circumstances. Some spoils, even though finely divided and showing dispersive tendencies, may contain a certain proportion of coarse gravel and the value of this should be recognized: Initially severe erosion may rapidly abate as the lag concentrate of surface gravel develops into stable mulch.

The placement of topsoil, although valuable, is not a requirement for reclamation success. The quality of topsoil

that has been stockpiled may deteriorate rapidly^[3] and the material often acidifies, requiring liming and fertilizer application to ensure optimal plant growth. The viability of seeds of many plants may decrease sharply after a few months of burial in a stockpile, and microbiological activity may also subside considerably. The importance of using freshly removed topsoil, therefore, needs to be emphasized by the rehabilitation specialist when dealing with mine planners.

In areas with insufficient topsoil, suitable waste rock or overburden is identified as a topsoil substitute. Such material will often be greatly improved by addition of organic matter and soil amendments such as lime (to neutralize acidity if the spoils are sulfidic) or gypsum (to improve permeability to water). Acidic rock drainage (ARD) can be particularly problematic in some mining wastes in view of the gradual nature of pyrite oxidation, leading to the slow release of acid, and the difficulty of accurately estimating the amount of lime needed for neutralization. Burial beneath 0.5 m or more of soil can be quite effective in minimizing ARD by cutting off a ready supply of oxygen from the pyritic soil.

The addition of fertilizers to topsoil substitutes may be needed until the nutrient cycle between soil and plants has been established. Slow-release formulations of nitrogen fertilizers may be especially valuable, although the cost may prohibit their use in some cases. A leguminous component in the vegetation cover can make a big difference to longer term nitrogen supply by harnessing the nitrogen-fixing capacity of symbiotic bacteria. Stimulating the population of soil fauna (e.g., bacteria, fungi, earthworms, termites, and rodents) is seldom pursued through direct inoculation or introduction of the desired species but can usefully be encouraged by understanding their special requirements (e.g., a suitable soil pH in the case of earthworms) and ensuring that these are met to some degree. The loosening and aerating effects of burrowing animal activity may well have been underestimated as prerequisites of successful rehabilitation. Even natural soils in their undisturbed state would tend, after long periods, to become increasingly compacted and structurally inferior were it not for the continual reworking of the soil by resident fauna.

REVEGETATION

The choice of vegetation cover depends on the end use, climatic conditions, and the potential productivity of the growing medium. Where cultivated crops, pastures, or forestry existed prior to mining, the goal is usually to restore productivity by re-establishing the same pattern of land use as far as possible. Often, the goal is partly aesthetic in achieving harmony with the surrounding landscape.

In many rehabilitation projects, it is desirable to reinstate the natural plant and animal communities of the area. This may be because the land is required for conservation or wildlife habitat purposes. Alternatively, it may be decided that natural plant communities will constitute the most

effective rehabilitation because of low maintenance requirements as well as resilience to drought and other extreme climatic events. Plant species in undisturbed ecosystems are an expression of the prevailing soil and climate. Consequently, if premining soil conditions can be approximated, plant species from surrounding natural areas are likely to be suitable for achieving revegetation of the disturbed area. Seeds should ideally be collected from areas that are as near to the rehabilitation site as possible to maintain the genetic integrity of surrounding ecosystems and to ensure that the reintroduced plants are adapted to the local conditions. The number of plant species and functional types on the rehabilitation site should preferably be maximized, given the ecological principle that ecosystem stability tends to increase with increasing biodiversity.^[4]

If topsoil is limited, it may not be possible to reinstate the local flora in its entirety. The chemical status of rock wastes is often not conducive to plant growth and if roots escape the topsoil layer and come into contact with high metal concentrations, acidity, alkalinity, or salinity of the waste materials, revegetation efforts may be thwarted. In such a situation, plant species should be carefully selected for their tolerance to the particular chemical conditions of the dump. Plant species that have colonized old dumps in the area are often suitably adapted to the chemistry of the waste material and constitute a valuable seed source for rehabilitation.

The rehabilitation of a waste dump and the maintenance of a recreated ecosystem may not depend solely on the reintroduction of local plant species. Effective management of the vegetation may include prescribing suitable fire regimes or herbivore stocking densities. Besides their bioturbation role mentioned above, invertebrates may also play a role in key ecosystem processes such as pollination, seed dispersal, and nutrient cycling. Provision of organic mulch on the soil surface can assist colonization of the soil by these invertebrates. Monitoring populations of invertebrates such as ants, nematodes, and spiders is useful for comparing rehabilitated land with adjacent ecosystems. Such studies can be used for assessing the extent to which the rehabilitation process is moving toward a premining ecosystem state.

ENSURING SUSTAINABILITY THROUGH AN UNDERSTANDING OF SOIL-FORMING PROCESSES

A key factor, of which reclamation ecologists are often unaware, is the value of studying natural soil profiles in the undisturbed landscape for clues as to the intensity of soil-forming processes that have given rise to the development of soil horizons. Features such as cemented calcic or duripan horizons in arid landscapes, plinthite in the subhumid tropics, and gleying in hydromorphic soils often reveal subtleties of climatic and topographic effects that are key ingredients in the functioning of the ecosystem. Inability to recognize their significance may doom the rehabilitation

effort to failure in the long run. In arid and semiarid ecosystems, a large proportion of nutrients supplied to roots from the mineralization of soil organic matter is derived from the top few centimeters of topsoil.^[5] This soil skin or pedoderm^[6] has various properties showing greatly enhanced expression relative to the bulk of the topsoil, such as content of organic matter and plant nutrients, activity of microorganisms, and stability of soil aggregates. It may also have features that are not evident in the remainder of the topsoil horizon, such as physical crusting, biological crusts, vesicular layers, bleaching, or salt crystals. The pedoderm is the interface between the atmosphere and the soil body and affects ecosystem function in a disproportionate manner because it controls water and air entry into the soil. Rehabilitation plans should take cognizance of its potentially critical role in sustaining ecosystem function and should aim to restore its unique physical and chemical characteristics.

CONCLUSION

Land disturbed severely through open-caste mining and other activities can be restored successfully by adhering to appropriate techniques and observing certain well-established principles of reclamation, which include the restoration of a growing medium for plants, the selection of vegetation species that is compatible with the local environment, and creating opportunities for a functioning, resilient ecosystem to develop as quickly as possible. Failure to either restore or simulate certain special features of the local soil, which existed prior to disturbance, such as less permeable or wetter layers within the profile as well as soil surface (pedoderm) characteristics, may make it impossible to mimic the original ecosystem.

Wastewater: Treatment and Utilization in Irrigation

Yona Chen

Jorge Tarchitzky

Department of Soil and Water Sciences, Faculty of Agricultural, Food and Environmental Quality Sciences, Hebrew University of Jerusalem, Rehovot, Israel

Abstract

Wastewater is predominantly utilized water discharged from municipal sewage water systems. Wastewater treatment is essential for the protection of public health and environmental quality. The effluent obtained after wastewater treatment is often utilized for irrigation. Attention has to be paid to various organic, inorganic, and microbial components in these effluents, since some are beneficial while others may adversely affect soil properties, crop quality and yield, or public health. These components in treated wastewater, regulations related to its utilization, and its potential desirable and adverse effects are discussed in detail.

INTRODUCTION

Wastewater or sewage water is utilized water discharged from homes, office buildings, cities, industry, and agriculture. Wastewater treatment is essential for the protection of public health and environmental quality. Treated wastewater (TWW; effluent) can be discharged in either rivers or the open sea, or can be utilized to irrigate agricultural crops. All these outcomes require a certain degree of treatment that will meet specific health and environmental standards. Large regions around the world, such as North Africa, the Middle East, and major parts of Asia, face severe water scarcity combined with the contamination of water resources. In a world where about 65% of total water withdrawal for human use is for irrigation, TWW reuse presents a highly desirable alternative with great potential for solving water shortages.

WASTEWATER CONSTITUENTS

The physical, chemical, and biological properties of wastewater are important parameters in the design of treatment facilities and are crucial in the prerequisite decision-making processes involved in building these plants. The major components of concern in wastewater are volatile and fixed suspended solids, biodegradable organics, pathogens (bacteria, viruses, and parasites), nutrients [nitrogen (N), phosphorus (P), and potassium (K)], heavy metals (e.g., cadmium, zinc, nickel, and mercury), refractory organics, and dissolved inorganics [total dissolved salts, sodium (Na), calcium, magnesium, chlorine (Cl), and boron (B)].^[1] The composition of untreated wastewater depends on the quality of the freshwater (FW) from which it comes and on the ratio between domestic, commercial, and

industrial wastewater in the treatment plant influent. The addition of chemical or biological components to FW during its domestic use is generally called “pick-up.” For some of the constituents, mainly organic materials, pathogens, nutrients, and heavy metals, their concentrations in raw wastewater are a direct result of the pick-up resulting from the specific use of the FW, because in FW they are usually negligible. In contrast, the concentration of dissolved inorganic solids (e.g., salts) is determined by their pick-up during FW use and by the composition of the incoming FW supply. The mineral pick-up in domestic water use in the United States has been reported to include 20–50 mg/L Cl, 40–70 mg/L Na, 150–400 mg/L total dissolved solids, and 0.1–0.4 mg/L B.^[1] These concentrations do not take into account the salt contribution of home water softeners. In Israel, the domestic salt increment is in the range of 80–100 mg/L Cl, 50–80 mg/L Na, and 0.1–0.3 mg/L B. The composition of domestic wastewater from a particular community is roughly constant over time. A typical composition of raw wastewater is presented in [Table 1](#).

WASTEWATER TREATMENT

The early objectives of wastewater treatment were 1) removal of suspended and floatable material; 2) treatment of biodegradable organics; and 3) elimination of pathogenic organisms.^[2] Later, the removal of nutrients such as N and P, as well as heavy metals, was also initiated, pursuant to environmental concerns. More efforts are focused on removing dissolved inorganic salts and organic micropollutants.

The treatments used to achieve the described objectives can be grouped into the following categories: 1) Physical: based on the application of physical forces such as

Table 1 Typical composition of untreated wastewater, TWW at different treatment levels and the overall removal.

Parameter	Raw wastewater	Primary effluent	Secondary effluent	Tertiary effluent	Overall removal
	mg/L				%
BOD (biological oxygen demand)	185	149	13	4.3	98
TSS (total suspended solids)	219	131	9.8	1.3	99+
Ammonia-N	22	21	9.5	9.3	58
Nitrate-N	0.1	0	0	0	0
Total Kjeldahl-N	31.5	30.6	13.9	14.2	56
Phosphate-P	6.1	5.1	3.4	0.1	98
B	0.35	0.38	0.42	0.31	13
Chloride	240	232	238	284	0
Na	198	192	198	211	0

Source: Modified from Metcalf & Eddy, Inc.^[2]

screening, mixing, flocculation, sedimentation, flotation, filtration, and gas transfer; 2) chemical: based on the addition of chemicals or on chemical reactions, such as precipitation, adsorption, and disinfection; and 3) biological: based on biological activity, used to remove biodegradable organic substances as well as nutrients (N and P).

Wastewater treatment plants most commonly employ a combination of different treatment units based on these principles, according to the desired quality of the TWW expected from the plant. The composition of raw wastewater, the resulting TWW quality after different levels of treatment, and the percentage removal of given components are presented in Table 1.

The conventional treatments are very efficient at removing organic components (chemical oxygen demand; biochemical oxygen demand—BOD), nutrients (N and P), and some of the heavy metals. In contrast, ions originating from mineral salts, such as chloride, Na, and B, are not removed during conventional treatments. Only advanced wastewater treatment plants can efficiently remove them.

TWW UTILIZATION

Following treatment, the effluent is transported to reservoirs and from there, when needed, to irrigation plots. Transport and distribution pipeline systems have to meet the following conditions: 1) clear and consistent identification of TWW pipelines and accessories via defined color coding (usually purple) and 2) a minimum horizontal separation between the TWW and FW pipeline systems to prevent cross-contamination, with separation distance varying according to local regulations (usually 3 m; 10 ft).

The TWW reclamation has to contend, via reservoirs, with the gap between TWW flow rate from the treatment plant and TWW demand by consumers. Wastewater flow has daily, weekly, and seasonal fluctuations. These fluctuations can be influenced by storm water inflow, seasonal changes in population due to tourism, or seasonal water

usage in industries. In addition, TWW demand fluctuates due to rainfall and crop water consumption.

REGULATIONS

TWW reuse regulations are based on several considerations and aspects, such as public health, defined utilization areas, environmental aspects, aesthetics, economics, public policy, and public acceptance.^[3] When crop irrigation is considered, the main concern is public health. In California, e.g., regulations are based on the concentration of total coliforms, water turbidity, and required treatment. For food crops, the requirements are 2.2 total coliform/100 ml, two nephelometric turbidity units, oxidation, coagulation, filtration, and disinfection. The World Health Organization guidelines are significantly less restrictive, with a requirement of 6–7 log pathogen reduction and ≤ 1 helminth egg per liter.

IRRIGATION WITH TWW

Nutrients of Importance to Plant Growth in TWW

TWW contains nutrients that are not present in FW, such as organic and ammonium-N, P, K, and micro-elements. N and P concentrations depend on the treatment level since their main source is organic, while K concentration does not change during treatment. It is, however, somewhat higher than in the FW source.

The N in sewage water is mainly organic (protein, amide, amino acid, and urea). Therefore, the main form of N in TWW is organic and ammonium-N. Different treatment plants employ different processes that may change the N forms in the effluent and in case of intensive aeration, nitrate-N appears as well.

P in sewage water and TWW also originates from organic compounds, and its concentration decreases with increasing treatment level. Fifty to ninety percent of the

total P in TWW is in soluble form. In plots irrigated with TWW, P is often applied in higher quantities than in plots irrigated with FW. Consequently, the P level in the soil in these plots may be higher^[4] than recommended for many crops. In plots irrigated with TWW, P may accumulate deeper in the profile. The vertical movement becomes more significant as the clay content in the soil decreases. Excessive P levels in soils may damage crops by inducing micronutrient deficiencies. It may also cause environmental damage by contaminating surface water and inducing eutrophication in water bodies.

K in sewage and TWW is a cation, and its source is pick-up of 5–15 mg/L.

Salt Content in TWW—Effects on Plant Growth

The quality of the TWW is an important factor in adapting its use for the farming community. Potential damage can be incurred by irrigation with low-quality effluents. The main effects to be taken into account are 1) total salt concentration—osmotic effect; 2) concentrations of chloride and B; 3) sodicity; and 4) hydrophobicity.

Total salt concentration—osmotic effect

As a general approximation, the pick-up value of the total salt concentration due to domestic use, measured by electrical conductivity (EC) of the water, is about 0.5 dS/m. This reflects all salts added to the FW supply during domestic and industrial activity. Excess salinity in the root zone adversely affects the growth of established plants as reflected by a general reduction in growth rate. Depression of the external osmotic potential by high salt concentrations tends to narrow the gap between the external (in the soil) and the internal (in the plant) water potentials. Salt stress essentially increases the energy that must be expended by the plant to extract water from the soil and to make the biochemical adjustments necessary for growth relative to non-saline conditions.^[5,6] Salinity effects are closely analogous to those of drought as both result in water stress and reduced growth. Maas and Hoffman^[7] proposed that the response curve be represented by two segments: one, a tolerance plateau with slope zero, and the other, a concentration-dependent line whose slope indicates the yield reduction per unit increase in salinity. The point at which the two lines intersect determines the threshold value. This two-section model provides a reasonably good fit for relative yields when plotted against the EC of the saturated soil extract (EC_s) in units of decisiemens per meter (dS/m). Thus, two values are needed to define a crop's sensitivity to salts: 1) the EC_s tolerance threshold and 2) the percent yield decrease per additional EC_s unit. Relevant tables are presented by Maas;^[8] e.g., avocado, representing a salt-sensitive crop, and cotton, a salt-tolerant crop, have threshold values of 1.0–1.3 and 7.7 dS/m,

respectively, and percent yield decreases of 15–20 and 5.2% per unit dS/m, respectively.

Specific toxicity

Specific toxicity differs from salinity (osmotic effect) in that it occurs within the plant itself and is not caused by a shortage of water. Toxicity normally results when certain ions are taken up with the soil water and accumulate in the plant (usually the leaves) during water transpiration, to an extent that results in damage to the plant. The degree of damage depends upon irrigation period, toxic agent concentration, crop sensitivity, and crop water use. Crop failure due to specific toxicity can be severe and at times lead to total loss. The most common toxic ions are chloride, B, and Na.^[9]

Chloride. Most herbaceous crops are not particularly sensitive to chloride. Woody plant species, on the other hand, are generally susceptible to chloride toxicity. Tolerance varies among species and even among varieties or rootstocks within species.^[10] The data presented in Table 2 indicate the maximum chloride tolerance concentration limits for some crops.^[11] These concentrations refer to saturated soil extracts and to soil concentrations. The concentration of soluble salts in the soil is a result not only of the chloride concentration in the irrigation water, but also of other factors such as soil texture, evapotranspiration, and irrigation management. For some crops, these concentrations may exceed the osmotic threshold.

Boron. Low concentrations of 0.5–1.5 mg/L B are essential for plant growth. B is needed for cell division and root tissue elongation and plays an important role in sugar

Table 2 Crop tolerance to chloride concentration in the saturated soil extract and in the soil.

Crop	Toxicity threshold		Crop	Toxicity threshold	
	mmol Cl/L ^a	mg Cl/kg soil ^b		mmol Cl/L	mg Cl/kg soil

transport. B deficiency causes anatomical, physiological, and biochemical changes in plants.^[12] Toxic symptoms of B are similar in most plant species, with the older leaves exhibiting them first. Initial visible symptoms include chlorosis, accompanied by necrosis of the edges and tips of the plant leaves. B concentration in leaves has been found to be in direct proportion to the B concentration in the soil solution.

Crops respond differently to B concentration in both the irrigation water and the soil solution. Accordingly, tables defining plant sensitivity to B in the irrigation water and soil solution have been published.^[5,13,14] Maas^[5] classified crops into groups according to their tolerance to B concentration in the irrigation water and in the soil solution (Table 3). The group of sensitive crops includes lemon, avocado, orange, grapefruit, apricot, peach, persimmon, grape, and onion, among others.

Salt Content in TWW—The Influence on Soil Physical Properties

Sodicity

An important concern in TWW irrigation is excessive Na concentration, which can result in structural deterioration of the soil. Excessive exchangeable Na allows swelling processes in clay minerals: aggregate stability is reduced and water infiltration rates decrease. This becomes a problem when the infiltration rate drops to levels at which the crop is no longer adequately supplied with water or when the hydraulic conductivity of the soil profile becomes too low to provide adequate drainage. A lack of oxygen to plant roots can also result. The sodium adsorption ratio (SAR) of irrigation water is generally a good indicator of the exchangeable Na status of the soil. Together with the adverse effects of sodic conditions, the presence of suspended solids and dissolved organic matter (DOM) in the effluents can affect the physical and hydraulic properties of the soil. In general, the SAR of TWW is higher by 1–3 units due to Na pick-up during domestic use.

A number of researchers have found reduced hydraulic conductivity in soils to which TWW was applied.^[15] Such changes may have physical, biological, or chemical causes.

Clogging of the soil surface layer has also been reported to result from the accumulation of suspended solids. Processes by which living organisms, bacteria in particular, influence soil hydraulic conductivity include slime production and accumulation under anoxic conditions, gas production, in particular by denitrifiers and possibly by methanogens, and plugging of the soil pores by bacterial cells.

Hydrophobicity

The coating of soil particles with DOM can change their surface area. Dissolved organic carbon adsorbs to the soil particles, and consequently, particle behavior may change. Farmers utilizing TWW in northern Israel reported a unique type of water distribution regime in drip-irrigated soils, consisting of 1) a limited wetted area on the soil surface and 2) small saturated areas around and below the dripper in the TWW-irrigated soil, in contrast to the even, onion-shaped wetting profile formed under FW irrigation. Following these observations in the field, it was hypothesized, then proven, that TWW irrigation introduces water-repellent organic constituents into the soil.^[16,17]

Tests performed to characterize the water distribution showed that the diameter of the saturated area on the soil surface and its water content (at a depth of 0–10 cm) were smaller with TWW than with FW irrigation. TWW accumulated on the soil surface in small lenses and then flowed rapidly into the ground. The repellency of soils irrigated with FW and TWW was measured using waterdrop penetration time and additional tests. Soils irrigated with FW were hydrophilic, whereas those irrigated with TWW exhibited hydrophobicity.^[17]

CONCLUSION

TWW is a valuable resource that has the potential to substitute much of the irrigation water used in agriculture. This substitution is essential for appropriate management of precious water resources, in particular in arid and semiarid countries. TWW is rich in nutrients, mostly N, P, and K, and therefore, its application requires adjustments on the farmers' side to avoid overfertilization and damage to the environment. Irrigation with TWW may also result in adverse effects on soil and groundwater quality. The most important factors that need to be addressed are mineral salts additions, chloride- and B-specific toxicity, enhanced SAR values, dispersive effects of DOM, DOM-induced hydrophobicity, and pathogens. Appropriate wastewater treatment practices, disinfection regulation, and caution can ensure that adverse effects are avoided.

Water Conservation

Paul W. Unger

Conservation and Production Research Laboratory, U.S. Department of Agriculture (USDA), Bushland, Texas, U.S.A.

Abstract

Soil–water conservation is important for crop production in all climatic regions but is critical in subhumid, semiarid, and arid regions. Increasing demands for water for agricultural and non-agricultural purposes make water conservation increasingly important in some regions. Improved soil–water conservation depends on increasing infiltration and reducing evaporation, transpiration (by weeds), and deep drainage losses.

INTRODUCTION

Although this entry emphasizes water conservation for agriculture, it is also important for residential, industrial, and recreational uses. Hence, all users should conserve water, especially where supplies are limited.

Adequate water is essential for optimum growth and development of all crops. For terrestrial crops, water is stored in soil between successive precipitation or irrigation events. Precipitation is usually adequate for crops in humid regions but becomes increasingly limited and erratic when going through subhumid and semiarid regions into arid regions. Periods without effective precipitation (precipitation that is beneficial to crops) often occur during the growing season of most crops in the drier regions. Ratios of precipitation to potential evapotranspiration are >0.75 , $0.50\text{--}<0.75$, $0.20\text{--}<0.50$, and <0.20 in humid, subhumid, semiarid, and arid regions, respectively.^[1]

In humid regions, plants seldom experience water deficiency because precipitation is usually frequent enough. However, even 7–10 days without rain may cause severe plant water deficiencies on soils having a low water-holding capacity. Major droughts cause severe damage regardless of a soil's water-holding capacity. Therefore, soil–water conservation is important in humid regions, especially where irrigation is not practiced.

Precipitation provides most water for crops in subhumid regions, with some water being available for irrigation. In semiarid regions where precipitation is more limited, crops often are irrigated where water is available. Precipitation is usually ineffective (of little or no benefit to crops) in arid regions, and irrigation is the prime water source for crops. Soil–water storage is essential for successful crop production under all climatic conditions, whether the water is derived from precipitation or irrigation, except with drip or daily sprinkler irrigation for which small amounts of water are applied frequently. Water conservation is important under irrigated conditions because of increasing

competition for water between agricultural, urban, industrial, and recreational users,^[2] especially where water supplies are limited or being exhausted.

SOIL–WATER CONSERVATION PRINCIPLES

Soil–water conservation is influenced by water infiltration into soil, evaporation from soil, use by non-crop plants (weeds), and deep drainage. To improve soil–water conservation, water infiltration must be increased, and losses because of evaporation, use by weeds, and deep drainage must be reduced.

Increasing Infiltration

Effective infiltration depends on soil conditions being favorable for adequate water flow into soil and on sufficiently slow runoff to provide adequate time for infiltration. Runoff water does not benefit crops unless captured downstream and subsequently used for irrigation. Runoff is eliminated when the infiltration rate equals or exceeds the precipitation or irrigation rate. Conditions favoring infiltration include the presence of a surface cover to intercept and dissipate the energy of raindrops, thus reducing soil aggregate dispersion and surface seal development that promote runoff; a rough soil surface that temporarily detains water and retards runoff; a soil profile free of horizons that impede water flow; and a low-antecedent soil–water content. Once a soil is filled to its storage capacity, no additional storage can occur. A soil's water storage capacity depends on its texture (sand, silt, and clay content), organic matter content, profile depth, and horizon characteristics. Water infiltrating a soil in excess of its storage capacity is lost by deep percolation unless an impermeable layer is present. When a soil becomes saturated, runoff will increase and some crops may be damaged.

Growing plants or crop residues (straw, stover, etc.) retained on soil through use of conservation tillage (reduced- or no-tillage) can provide a surface cover. Besides reducing the adverse effects of raindrops striking the surface, such cover also retards the rate of runoff across the surface, thus providing more time for infiltration. Growing plants use soil water and, therefore, the soil is usually drier, which increases the potential for infiltration. Other means to reduce runoff and increase infiltration include tillage to disrupt surface seals caused by previous precipitation, create depressions for temporary water storage on the surface (surface roughness, contour tillage, and furrow diking), reduce the rate of runoff from the surface (graded furrow), and disrupt restrictive layers in the soil profile (deep plowing or chiseling). Infiltration may also be increased by applying phosphogypsum (PG) to the soil surface^[3] and injecting an anionic polymer into irrigation water,^[4] which stabilizes the soil surface.

Reducing Evaporation

Soil–water losses by evaporation are the greatest during first-stage evaporation, which depends on the net effect of water flow to the surface and environmental conditions (wind speed, temperature, relative humidity, and radiant energy). Losses decrease rapidly during second-stage evaporation when the soil–water supply decreases, and the rate depends mainly on soil conditions that control water flow to the surface. Third-stage evaporation is low and controlled mainly by adsorptive forces at the solid–liquid interface. Water moves to the surface as vapor in the third stage. The potential for decreasing evaporation is the greatest during the first stage.^[5] Practices that decrease evaporation include decreasing turbulent water vapor transfer into the atmosphere, decreasing capillary continuity or water flow to the surface, and decreasing the water-holding capacity of the surface soil layer. A reduction of turbulent transfer of soil water to the atmosphere is most easily achieved by applying a surface mulch. Many materials can serve as a mulch,^[6] but crop residues and plastic films are most commonly used. Shallow tillage can reduce capillary water flow to the surface and, therefore, reduces the evaporation of soil water under some conditions.

Reducing Use by Non-Crop Plants (Weeds)

Soil water transpired by weeds (including volunteer crop plants) hinders crop production under most conditions. Weeds present before planting decrease the soil–water supply for later crop use, while those present during the growing season compete directly with crops for soil water, space, light, and nutrients. Effective weed control is especially important for dryland (non-irrigated) crops^[7] and efficient use of irrigation water.^[2] Weeds can be controlled with tillage, with the applications of appropriate herbicides, or by hoeing.

Reducing Deep Drainage

Deep drainage occurs when infiltrated precipitation or irrigation water exceeds a soil's water storage capacity. Such drainage reduces the amount that crops can use because it penetrates to depths beyond crop rooting depths. The water may also move some nutrients beyond the rooting depth, thus resulting in inefficient use of applied nutrients and possibly polluting underground water supplies.

To reduce drainage losses, crop-growing seasons should closely match the season when the potential for excess water is the greatest. Encouraging deeper plant rooting, as with deep tillage, and planting deep-rooting crop species also reduces deep drainage. Precipitation cannot be controlled, but irrigations at timely intervals using appropriate amounts of water can minimize the losses. Other practices include deep plowing to bring materials to the surface that retain more water,^[8] installing subsurface barriers,^[9] and adding organic matter to increase the water-holding capacity.^[10,11]

SOIL–WATER CONSERVATION ACHIEVED UNDER DIFFERENT CONDITIONS

Extensive soil–water conservation research has been conducted, but only a few examples will be given because of space limitations. Under semiarid conditions at Bushland, Texas, U.S.A., moldboard-, rotary-, disk-, sweep-, and no-tillage treatments were imposed after harvesting irrigated winter wheat (*Triticum aestivum* L.) to manage the residues during the fallow period until planting dryland grain sorghum [*Sorghum bicolor* L. (Moench)] 10–11 months later.^[12] Plant-available soil–water contents averaged 149, 143, 158, 179, and 207 mm at sorghum planting, and sorghum grain yields averaged 2.56, 2.19, 2.37, 2.77, and 3.34 Mg/ha with the respective treatments. Greater water contents and yields with sweep-tillage and especially no-tillage resulted from more residues retained on the surface than with other treatments during fallow and the sorghum-growing season. The residues resulted in greater infiltration and lower evaporation, but the individual contribution of these processes could not be determined. Weed control was similar with all treatments, and deep drainage was too small to affect the results.

Soil–water contents were similar to the 15 cm depth one day after a 13.5 mm rain at Akron, Colorado, U.S.A., where conventional-, minimum-, and no-tillage treatments were imposed after harvesting winter wheat. Residue amounts were 1.2, 2.2, and 2.7 Mg/ha with the respective treatments. After 34 rainless days, water contents were $<0.1 \text{ m}^3/\text{m}^3$ to 12, 9, and 5 cm depths with conventional-, minimum-, and no-tillage, respectively.^[13] This field study clearly showed the value of surface residues for reducing evaporation, which was also shown under laboratory conditions.^[14,15] Under no-tillage conditions in Colorado,

increasing the cropping intensity from a wheat–fallow to a wheat–corn (*Zea mays* L.) or sorghum–fallow system resulted in a drier soil root zone. This, in turn, resulted in storing more water from precipitation in the soil because of greater infiltration and lower soil–water evaporation and deep drainage.^[16]

When PG was applied at 10 Mg/ha to a ridged sandy soil in Israel, runoff was reduced sixfold as compared with that from untreated soil.^[3] This showed the value of a soil-stabilizing material for reducing runoff and increasing infiltration. When PG was applied at 3 Mg/ha to a clay loam under laboratory conditions, runoff was less than that from bare soil but greater than where wheat straw was applied at 2.2 Mg/ha.^[17] Injecting anionic polymers into water used for furrow irrigation on a silt loam in Idaho reduced soil loss of 70% when applied at 0.7 kg/ha per irrigation and 97% when applied at 10 g/m³ of water. Infiltration was increased probably because surface sealing and sediment transport were reduced.^[4,18]

CONCLUSION

Soil–water conservation is important for crop production in all climatic regions but is critical in subhumid, semiarid, and arid regions. Increasing demands for water for agricultural and non-agricultural purposes make water conservation increasingly important in some regions. Improved soil–water conservation depends on increasing infiltration and reducing evaporation, transpiration (by weeds), and deep drainage losses. Practices for increasing infiltration include keeping the soil covered with plants or a mulch to reduce surface seal development and to impede runoff; applying materials to stabilize the soil surface; and using tillage to disrupt sealed soil surfaces, provide for temporary depressional water storage on the surface, and disrupt subsurface layers that impede water movement. Evaporation can be reduced by a surface mulch (crop residues or plastic films) or by a shallow tillage. Weeds can be controlled by tillage, herbicides, or hoeing. Deep drainage can be minimized by matching crop-growing seasons to seasons when water excesses are most likely increasing soil–water storage capacity, loosening the soil to allow deeper plant rooting, planting deep-rooting crops, and installing subsurface barriers that impede deep drainage.

Water Content

Tom J. Jackson

Hydrology Lab, U.S. Department of Agriculture—Agricultural Research Service
(USDA-ARS), Beltsville, Maryland, U.S.A.

Abstract

Soil water content is a basic hydrologic state variable. It is used in applications that range in scale from irrigation management to flood forecasting. Soil water content has also increased in importance in weather forecasting and climate modeling, as these disciplines have begun to recognize its importance in large-scale water cycles.

INTRODUCTION

As important as soil water content is in human activities and food supply, it has not been as widely observed and monitored as other variables such as precipitation and temperature. This is caused by inadequate instrumentation as well as the numerous scales of variability that affect this state variable.

Soil water content generally refers to the volumetric soil water content. This is the percentage or fraction of a known volume occupied by water (θ_v). This is related to the gravimetric soil water (θ_g) and the bulk density of the soil (ρ_{soil}).

$$\theta_v = \frac{\theta_g \rho_{\text{soil}}}{\rho_{\text{water}}} \quad (1)$$

Soil bulk density is the mass of dry soil within a known volume. Typical values will range from 1 to 1.5 g/cm³. The measurement and estimation of ρ_{soil} are described elsewhere in this encyclopedia as well as in the study by Grossman and Reinsch,^[1] ρ_{water} is the density of water and is close to a value of 1 g/cm³ and is usually dropped from the equation.

VARIABILITY AND SAMPLING

A problem with both characterizing and sampling soil water content is that it exhibits variability that is related to physical characteristics and forcing variables that vary on scales of soil pores to continents. These sources and scales are discussed in further detail in the work done by Hawley et al.,^[2] Kutilek and Nielsen,^[3] Warrick and Van Es,^[4] and Vinnikov et al.^[5] At the field scale, important factors are the soil texture, vegetation, and topography. The next level is related primarily to precipitation and to a lesser degree to evapotranspiration. Finally, larger scale climatology will influence soil water content over regions and continents. From these works, it is evident that variations within a field can be as large as within a 100 km region.

METHODS FOR MEASURING SOIL WATER CONTENT

There is a wide range of techniques available for measuring soil water content. These are described in depth in the work done by Kutilek and Nielsen,^[3] Campbell and Mulla,^[6] Topp and Ferre,^[7] Hillel,^[8] and Or and Wraith.^[9] Some of these are reviewed in the following section. It is important to note that there is no universal standard method (gravimetric with oven drying is the closest). This is because of the difficulties in capturing the variability, instrument design, and logistics. The advantages and disadvantages discussed in the following sections are summarized in [Table 1](#).

Gravimetric Sampling and Oven Drying

Gravimetric sampling combined with oven drying is generally accepted as the standard technique for characterizing soil water content. In this approach, a sample from a specific depth interval is removed from the field and placed in a container of known tare weight. The sealed sample is weighed, opened, and placed in an oven at 105°C for 24 hr. It is then weighed again. The gravimetric soil water content is computed as follows

$$\theta_g = \frac{\text{Wet weight} - \text{dry weight}}{\text{Dry weight} - \text{tare}} \quad (2)$$

If the sample is collected using a tool of known volume, the volumetric soil moisture can be determined directly.

$$\theta_v = \frac{(\text{Wet weight} - \text{dry weight})/\rho_{\text{water}}}{\text{volume}} \quad (3)$$

Otherwise, an estimate of the bulk density must be used to convert θ_g to θ_v .

Coring tools can be used to extract a sample of known volume. This method works well for small diameter samples from moderate depth intervals on compacted soils.

Table 1 Comparison of some methods of measuring soil water content.

Technique	Advantages	Disadvantages
Gravimetric	Only method providing a direct measurement	Destructive
	Inexpensive equipment	Labor required
	Accurate	Time delay for drying
TDR		Small sample size
	Most accurate indirect method	Expensive
	Rapid	Salinity
Capacitance	Some spatial averaging	Depth resolution for surface layer
	Low cost	Sensitive to installation
	Rapid	
Heat dissipation	Probe design very flexible	
	Low cost	Limited range of moisture
	Easy to install	Calibration hysteresis
Radioactive source	Provides water potential	Small sampling area
		Slow response
	Some spatial averaging	Radiation hazard
Remote sensing		Expensive
		Calibration
		Can't measure surface layer
	Local, regional, and global mapping	Poor spatial resolution
	Spatial averaging	Only surface information

For instance, it is difficult to sample shallow surface layers on tilled soils with this method. Scoops and augers can be used to collect gravimetric water content samples. Many of these devices can be seen at the following web site: <http://www.soilsample.com/>.

As noted in methods manuals, care must be exercised when using this method. Samples should be over 100 g, and consideration should be given to the general soil conditions and oven conditions when choosing a drying period. The major drawback to gravimetric sampling is that it is time consuming. In addition, it is destructive. Repetitive sampling at a location could modify conditions.

In Situ and Portable Measurement Techniques

A brief overview of these methods is presented here. An excellent source of additional information is the web site (<http://www.sowacs.com/>), which includes links to manufacturers as well as comparisons.

Time domain reflectometry

Time domain reflectometry instruments represent a fairly advanced technology at this point in time. These devices are capable of measuring two properties of the soil, namely, apparent dielectric constant and conductivity. The discussion here only considers the dielectric constant.

The soil dielectric constant is a function of the volume fractions and dielectric constants of its constituents: water, soil, and air. There is a very large difference between the dielectric constants of water and the other components, which makes these devices highly sensitive to soil water content.

A time domain reflectometry (TDR), as typically used in soil water devices, measures the time it takes for an electrical wave to travel down parallel rods and reflect back. The rods are embedded in the soil and can be used *in situ* or as a portable sensor. The travel time will vary with the sensor configuration and the dielectric properties of the media. There are limitations on how short and how long the rods can be.

Ferre and Topp^[10] and numerous other investigators have found that, for most field soils, a single calibration function can be used. When the soils have high clay contents (or organic matter), a separate calibration is required.^[11]

Therefore, TDR is a relatively robust method for measuring soil water content and can be incorporated as an *in situ* or as a portable sensor. Earlier system designs used low-cost sensors with a relatively expensive cable tester unit. Newer designs include all components in each individual sensor at a modest cost.

Capacitance devices

The dielectric constant of the soil media can also be measured using capacitance sensors. As described above, this dielectric constant is a function of the volumetric soil water content. A capacitance sensor consists of two or more electrodes with the soil media between them. An electronic oscillator is used to determine the oscillator frequency, which is a function of the dielectric constant (as well as the probe configuration).

These devices have become quite popular, and there are several commercially available systems. One difference between these systems is the capacitor design, which affects the way the device can be used. Some devices utilize horizontal plates separated by a low dielectric material. This probe unit is placed in a low dielectric tube (polyvinyl chloride pipe) installed in the soil. Probes can be left in place for *in situ* measurement^[12] or used in a fashion similar to neutron probes, carrying from site to site and logging the profile as the probe is lowered in the tube.

Another capacitance sensor design utilizes parallel rods.^[12] These can be used as *in situ* or portable sampling

Fig. 1 A handheld capacitance type soil water content probe.

tools. One advantage of this device as opposed to the TDR is that shorter rods can be used (5–6 cm are typical). This means measurement closer to the soil surface is possible and that there are likely to be fewer problems when the device is used as a portable surface sampler. Fig. 1 shows a handheld portable version of the capacitance probes. Capacitance probes will be subject to the same calibration problems as TDR devices as related to soil texture and possible mineralogy. Most instruments are supplied with a general calibration.

Heat dissipation

The thermal conductivity of a soil is a function of its water content. Heat dissipation sensors are based on this relationship.^[13] A heater and a thermocouple are embedded in a ceramic probe and placed in the soil. The initial temperature is recorded, and then the heater is turned on for a short period of time and the final temperature is recorded. The change in temperature is related to the soil water content. The ceramic probe is assumed to be in matric potential equilibrium with the surrounding soil. This device is generally used to measure the matric potential and not the soil water content. Once calibrated for matric potential, the probe can be installed in any soil. However, to obtain soil water content, the probe must be either calibrated for the particular site or the matric potential must be related to soil water content using additional calibration or pedotransfer functions.

Radioactive source devices

These methods have been in use for a number of years.^[14] One of the most common is the neutron probe. Here a radioactive source and a detector are lowered down a tube in the soil. Water within the sphere of influence affects the response (neutron scattering). Another radioactive device is the gamma attenuation probe. A source is lowered down a tube while a detector is lowered down a parallel tube. The attenuation is related to the water content. Considering the range of low cost, reliable alternatives available, and the risks associated with radiation, radioactive source methods are not recommended.

Remote sensing

Remote sensing refers to non-contact methods that generally utilize responses within portions of the electromagnetic spectrum. For soil water content measurements, the soil can be viewed from the surface, using these devices. Sensors can be installed on towers, aircraft, and satellites. A key advantage of remote sensing is that systems can be designed to map large regions quickly on a frequent basis.

Although all regions of the electromagnetic spectrum have been explored for soil water measurement,^[15] only microwave techniques can provide a robust measurement. Microwave sensors appropriate for soil water content measurement can see through clouds and most vegetation. Observations can be made at any time of day as solar illumination isn't required. The microwave signal originates within a depth of the surface soil. The lower the frequency used, the deeper is the depth. However, there are restrictions on the frequencies that can be used, which limit this depth to approximately 5 cm.

Two methods can be used, namely, active and passive. Active methods or radars send out a microwave signal, which interacts with the earth's surface (soil and vegetation). A portion of this signal is reflected back to the sensor. The response depends upon the dielectric properties of the soil, among other factors. As described previously, the dielectric properties are functionally related to the soil water content.

Passive methods measure the earth's natural emission at these frequencies. This emission is called the brightness temperature, and it depends upon the physical temperature and the emissivity. Emissivity is a function of the dielectric constant and thus soil water content.

The examples of soil moisture maps derived over a portion of Oklahoma are shown in Fig. 2.^[16] These cover a watershed (600 km²) at a spatial resolution of 200 m. Here the patterns are related to soil type differences that affect the soil water content. The other image is of the same region (10,000 km²) at a spatial resolution of 800 m. Here the spatial patterns are dominated by rainfall features.

DATA SOURCES

For the reasons discussed in the previous sections, there have been few attempts to measure soil water content on a routine basis such as is done with precipitation. Therefore, there are very few data resources and networks. Much of the historic records have been compiled in the study by Robock et al.,^[17] as part of the Global Soil Moisture Data Bank. This information can be obtained through the following website: http://climate.envsci.rutgers.edu/soil_moisture/.

The entry done by Robock et al.^[17] also describes most of the existing networks that collect soil moisture data. Of these, the soil climate analysis network (SCAN) operated

Fig. 2 Soil moisture maps for the Little Washita Watershed, Oklahoma, 1992.

by the U.S. Department of Agriculture is the most readily available. SCAN provides real time and historic (a few years at this point) hourly soil moisture and meteorological data at over 30 stations in the United States. These data can be obtained through the following web site: <http://www.wcc.nrcs.usda.gov/scan/>.

Remotely sensed soil moisture data sets from several previous experiments are available from the following web site: <http://hydrolab.arsusda.gov/>. In addition, since 2002 the Aqua satellite has been producing a global soil moisture product (<http://nsidc.org/daac/amsre/>).

CONCLUSION

In situ soil moisture technology has advanced in years. However, the proliferation of techniques and fundamental differences in the physical characteristic measured has contributed to the lack of standards and transferability of results. There is a great need for improved best practices.

At the present time, the capacitance type probes appear to be a robust approach.

A major change that will occur over the next years is the implementation of satellite remote sensing systems dedicated to the measurement of soil moisture. These include the National Aeronautics and Space Administration Hydros mission^[18] and the European Space Agency Soil Moisture Ocean Salinity Mission.^[19] Routine, daily global mapping of soil moisture, especially if supported by *in situ* soil moisture networks, will benefit many applications.

Abstract

Soil moisture measurement with *in situ* methods over large areas and at frequent time intervals is not practical for most purposes. Remote sensing from air- and space-borne platforms permits data collection from large areas and at frequent time intervals, matching the dynamic nature of soil moisture. Remote sensing with the microwave spectrum, wavelengths ranging from 1 mm to 1 m, is attractive as data can be collected day or night and through clouds. Terrestrial applications of microwave sensing typically use wavelengths from 3 to 75 cm, although the convention of microwave remote sensing is to refer to frequency rather than wavelength. The topic of microwave sensing is a broad one as it not only includes two general types of instruments, but also a variety of applications spanning fields such as agronomy, soil science, hydrology, meteorology, and astronomy.

INTRODUCTION

This discussion will only include passive microwave sensing, synthetic aperture radar (SAR), and their use for detecting soil moisture. There are other types of radar instruments; however, only SAR systems have come to be widely accepted for terrestrial applications. Active and passive microwave systems are briefly described, excluding many critical details about instruments, data collection and processing, and applications. The reader should consult Ulaby et al.^[1–3] for a comprehensive examination of many of these issues. More brief, but very informative, descriptions are available from the work of Elachi,^[4] Rees,^[5] and Lillesand and Kiefer.^[6]

THE PHYSICAL BASIS FOR MICROWAVE REMOTE SENSING OF SOIL MOISTURE

Microwave remote sensing is similar to sensing in other parts of the electromagnetic spectrum in that a sensor is used to detect the results of the interaction of energy from a part(s) of the electromagnetic spectrum with some type of media. Soil is a composite media of solid, water, and air components. As the amount of water in the soil changes, the emission and reflection of energy from the soil also change. The influence of soil moisture on emission and reflection is described numerically by the

dielectric constant. Although the dielectric constant is referred to as a constant, it actually changes with the amount of water in the soil and is indicative of the differences in dielectric properties of dry soil and water. For example, the dielectric constant of water is around 80, while those of soils can vary from 3 (very dry soil) to around 30 (very wet soil).

Fig. 1 shows the change in dielectric constant with volumetric soil moisture at different frequencies for one texture. Most applications of microwave sensing address soil moisture on a volumetric basis to minimize differences due to texture. As can be seen, the relationship between dielectric constant and volumetric moisture content is nonlinear. The rapid increase in dielectric constant with volumetric moisture content can be attributed to the amount of water in direct contact with the soil. At drier moisture contents the water is bound more tightly to the surface of the soil particles, which limits their ability to propagate energy. As the moisture content increases, the water is less bound and permits energy to propagate more freely resulting in an increase in dielectric constant. As can be seen, the dielectric constant is described by a real (ϵ') and an imaginary (ϵ'') component. The real dielectric constant is that which describes the propagation of the energy at a given wavelength or a range of wavelengths. The imaginary part of the dielectric constant describes losses, like friction in which energy is converted to heat, that occur during the interaction of a wave with a material.

Fig. 1 Variation of dielectric constant with volumetric soil moisture.

Source: Adapted from Lillesand & Kiefer.^[3]

While both passive and active microwave remote sensing of soil moisture are based on the dielectric properties of soil, the physical mechanisms that are the basis for detection by these instruments are very different. A brief background to passive and active microwave sensing is provided as preparation for a description of the application of the instruments for soil moisture detection.

SAR SYSTEMS AND DATA

Active microwave systems employ RADAR, an acronym for radio detection and ranging, technology for generating radio waves for illuminating areas or objects. The radio waves are directed away from a source antenna, which is also used to detect waves reflected from incident surfaces. Fig. 2 shows the general operation of a RADAR system, in this case a side looking airborne radar (SLAR). The detection of reflected waves does not have to be done by the same antenna that generated them, but nearly all commercial and government systems use this approach.

Pulses of known electromagnetic properties are generated by the RADAR hardware and propagated by the antenna. End-to-end knowledge of pulse electromagnetic properties is the foundation of SAR data processing, which can produce the fine azimuth resolution that differentiates SAR from real aperture RADAR systems. The pulse properties on reception provide information about an area from which they were reflected. An area is illuminated by many

pulses as the antenna is moved along a trajectory. SAR processing takes the intensity of each received pulse and sums them. Pulses can contribute positively or negatively depending on the wave properties at detection. Ultimately, an image of values is assembled, indicative of the intensity of the energy received at the antenna and the output of the summation operation executed during processing. Graphically, an image is composed of pixels, giving SAR data an appearance similar to that acquired by the SPOT and Thematic Mapper optical and near-infrared instruments.

The magnitude of the intensity values, also called the backscatter cross-section, in an image is the result of the interaction of the transmitted pulses with the scattering and dielectric properties of the object(s) encompassed in the area defined by a pixel. Fig. 2^[4] shows the difference between the intensity of pulses received from different features present in one image line. For example, the hill has the largest cross-section of all features imaged. The cross-section does not necessarily have to be related to a feature's size. There are conditions in which relatively few small scattering surfaces can generate a large cross-section. Factors influencing backscatter cross-section include surface conditions (soil roughness, soil moisture, and vegetation density and canopy properties) and illumination characteristics (incidence angle, azimuth angle, wavelength, and polarization).

Some additional processing is done to yield an image of values known as the normalized backscatter cross-section. Backscatter cross-section is a ratio of power received over that incident on a surface and also includes antenna and illumination characteristics. For terrestrial applications, backscatter cross-section is usually normalized by the area spanned by the pulses of power summed for each pixel in an image. Targets with area are referred to as distributed, due to the spread of transmitted power across the earth's surface. The spread of power over an area matches the extensive arrangement of most terrestrial targets, such as crop and tree stands.

The normalized backscatter cross-section is a dimensionless quantity equal to the average cross-section per unit area. Normalized backscatter cross-section can vary over orders of magnitude, hence is usually calculated in decibels (10 times the log backscatter cross-section). Note that the normalized backscatter cross-section is the ratio of average scattered power density over the average incident power density over the scattering surface. It is not the total scattered power divided by the total incident power, which means that the normalized backscatter will vary with different incidence and azimuth angles and can be greater than 1 for certain orientations.

PASSIVE MICROWAVE SYSTEMS AND DATA

Passive microwave sensing is based on the detection of radiation by an antenna that is constructed only to

Fig. 2 SLAR instrument operation and data processing.

Source: Adapted from Ulaby, Moore, et al.^[6]

receive energy. The passive instrument then detects the intensity of microwave energy that originates from a source that is not the antenna. Passive instruments are referred to as radiometers, the same terminology used for thermal instruments sensitive to shorter wavelengths. Passive microwave and shorter wave thermal radiometry share many of the same physical and instrument concepts.

The basic structure of a microwave radiometer is shown in Fig. 3. The passive microwave radiometer has three major components. The first component is an antenna that receives the incoming energy for a given instrument orientation. The second component is a receiver that detects and amplifies the signal from the antenna. The receiver is designed to be sensitive to energy of a selected frequency range and polarization.

The third component of a microwave radiometer is a data handling system that has two major parts, a switch and a data recorder. The switch alternately passes data to the data recorder from the receiver and a thermal reference. Data from the receiver are in units of V. The thermal reference attains the temperature that occurs at the surface in order to achieve the detected voltage at the antenna. The nearly simultaneously acquired signals allow for the determination of the apparent antenna temperature, which is a conversion of the antenna acquired voltage to temperature, usually expressed in K. Other recorded data assist post-processing, including antenna pattern and atmospheric corrections. After post-processing, the apparent temperature of the antenna is converted to a quantity referred to as brightness temperature.

Fig. 3 Passive microwave radiometer sensing system.

Source: Adapted from Lillesand & Kiefer.^[3]

If a scanning radiometer is used to acquire data, then an image can be constructed from the brightness temperature values. The passive microwave image is composed of pixels, the same structure as described for SAR images. Energy detected with passive microwave instruments is low in power and, hence, the spatial resolution of the acquired images is very coarse when compared to SAR systems, usually in the range of kilometers for orbiting instruments.

In the absence of instrument effects, brightness temperature is the product of radiation from sunlight reflected by the earth and atmosphere, and energy emitted from the earth's surface (Fig. 4). For frequencies used for terrestrial

Fig. 4 Signal components for passive microwave sensing.

Source: Adapted from Ulaby, Moore, et al.^[6]

remote sensing, the contribution from the atmosphere is negligible. Reflection and emission from the earth's surface are then the dominant sources of radiation detected by the antenna. Given the variety of sources of energy detected at the antenna, the application of brightness temperature for soil moisture sensing can be complicated. One similarity between brightness temperature and backscatter cross-section is that they are influenced by the same scene and illumination factors.

SOIL MOISTURE SENSING WITH SAR AND PASSIVE MICROWAVE INSTRUMENTS

Many investigations have established the sensitivity of normalized backscatter cross-section and brightness temperature to soil moisture. However, passive microwave brightness temperature and SAR normalized backscatter cross-section are also influenced by soil roughness and vegetation, which complicates the soil moisture detection. It is not possible to describe passive and active sensing of soil and vegetation thoroughly here, but more complete reviews of these sensitivities can be found in the work of Engman,^[7] Engman and Chauhan,^[8] Schmugge et al.,^[9] and Schmugge.^[10] A quick summary of these would imply that backscatter and brightness temperature increase with soil moisture and roughness, and vegetation canopy density.

However, the exact nature of the relationship between normalized backscatter cross-section and brightness temperature, and soil moisture and roughness, and vegetation canopy is also highly dependent on illumination factors (incidence angle, instrument frequency, and polarization, etc.). Also note that soil and vegetation vary greatly over short distances and are independent of each other, further complicating the interpretation of active and passive microwave data. The emphasis of the research is to quantitatively estimate soil moisture from normalized backscatter cross-section and brightness temperature even given the difficulties presented by the soil moisture sensing problem. It is hoped that remotely sensed estimates of soil moisture can be used for applications such as crop management, flood prediction, and regional and global hydrologic research.

Quantitative Soil Moisture Estimation

A variety of modeling approaches have been used to quantitatively estimate soil moisture from SAR normalized backscatter and passive microwave brightness temperature. No approach has been found to be universally applicable. The development and evaluation of quantitative soil moisture algorithms are hampered by the need for extensive supporting ground and sensor data.

The most rigorous investigations have been undertaken through the coordinated effort of a few organizations using airborne multiinstrument sensing of an area, which is

simultaneously sampled for a number of soil and plant properties. The Wahita '92 and '94 programs, using a study area in south-central Oklahoma, are excellent examples of such efforts. Summary of the programs, references to published articles and access to generated data are available through the World Wide Web at <http://hydrolab.arsusda.gov>. Jackson et al.^[11] realized promising results from an airborne passive microwave investigation to estimate soil moisture over a large area of the same section of Oklahoma. See van Oevelen and Hoekman,^[12] for a description of the use of airborne and orbiting SAR instruments to predict soil moisture of sites in Spain and the Sahel.

Progress in the quantitative estimation of soil moisture has also been hindered by the instruments used to collect data. For example, the only orbiting SAR instruments are single frequency/polarization, which restricts the information that can be extracted from the collected data. The lack of information can be compared to attempting to conduct land cover investigations from a single band instrument that only collects data in the green portion of the spectrum. Orbiting passive microwave instruments acquire multifrequency data; however, the spatial resolution of the data is coarse and the frequencies are not ideal for soil moisture detection. The estimation of soil moisture from spaceborne instruments will then rely on having the right instruments as much as having an appropriate method.

Water Erosion

David Favis-Mortlock

Environmental Change Institute, University of Oxford, Oxford, U.K.

Abstract

Erosion by water is the redistribution and removal of the upper layers of the soil, both by the action of falling rain and by water flowing over the soil during and after rain or following snow melt. It occurs on both agricultural and undeveloped landscapes. While erosion by water is a natural phenomenon, removal of the soil's protective cover of vegetation at times of heavy rains greatly increases erosion rates, so that they exceed rates of soil formation. This is known as accelerated erosion and is always the result of human actions such as unwise agricultural practices, overgrazing, or construction activity. Accelerated water erosion is a problem over much of the earth's surface and has both on-site and off-site impacts. The main on-site impact is the reduction in soil quality which results from the loss of the nutrient-rich upper layers of the soil and the reduced water-holding capacity of many eroded soils. In affluent areas of the world, accelerated water erosion's on-site effects upon agricultural soils can be mitigated by increased use of artificial fertilizers; however, this is not an option for much of the earth's population. Water erosion's main off-site effect is the movement of sediment and agricultural pollutants into watercourses, leading to the silting-up of dams, disruption of the ecosystems of lakes, and contamination of drinking water. In some cases, increased downstream flooding may also occur due to the reduced capacity of eroded soil to absorb water.

PROCESSES OF EROSION BY WATER

Water erosion is driven by the gravitational energy of rain-fall and flowing water. When rain falls upon unprotected soil, its kinetic energy may detach soil particles, and this is one of the subprocesses^[1] of water erosion (RD-ST in Fig. 1) and is often referred to as “rainsplash erosion” or “splash erosion.” A more accurate term is “rainsplash redistribution,” since although considerable quantities of soil can be moved by splash, almost all of it is merely redistributed on the soil's surface, i.e., the net downslope movement of splashed soil is generally small. Rainsplash redistribution is most effective where rainfall intensities are high,^[2] e.g., as a result of convective rainstorms in the world's equatorial regions. Low-intensity rainfall is often of frontal origin. Where such rainfall is common (e.g., northwest Europe), rainsplash is ineffective.

Some of the rain may infiltrate into (i.e., be absorbed by) the body of the soil. In dry conditions, all rain will infiltrate: the result is then rain with no runoff (Fig. 1). Runoff, that part of the rainwater which has not infiltrated, tends to flow downhill under the action of gravity. This thin diffuse film of water has lost virtually all the kinetic energy which it possessed as falling rain, thus it moves only slowly, has low flow power, and is generally incapable of detaching or transporting soil particles (“no erosion” in Fig. 1).

The microtopography (i.e., small-scale pattern of irregularities) of the soil's surface tends to cause this overland flow to concentrate in closed depressions which slowly fill, and this is known as “detention storage” or “ponding.”

Both the flowing water and the water in detention storage protect the soil from raindrop impact, so that rainsplash redistribution usually decreases over time within a storm as the depth of surface water increases. There are, however, complex interactions between rainsplash and overland flow (Fig. 1).

If the rain continues, the increasing depth of water will eventually overtop the depressions. Overland flow that is released in this way is likely to flow downhill more quickly and in greater quantities (i.e., possess more flow power as a result of its kinetic energy) and so may be able to begin transporting (RD-RIFT, RD-FT and FD-FT in Fig. 1) and even detaching (FD-FT in Fig. 1) soil particles. Where it does so, the soil's surface will be lowered slightly. Lowered areas form preferential flow paths for subsequent flow, and these flow paths are in turn eroded further. Eventually, this positive feedback^[3] results in small, well-defined linear concentrations of overland flow (“microrills” or “traces”).

In many cases, individual microrills become ineffective over time due to sedimentation. A subset, however, grow further to become rills^[4] and a smaller subset may go on to develop into gullies. This process of “competition” between microrills and rills leads to the self-organized formation^[3] of networks of erosional channels (dendritic on natural soil surfaces;^[5] constrained by the direction of tillage on agricultural soils^[6]), which form efficient pathways for the removal of water from hillslopes. It is in such erosional channels that water erosion also operates most effectively to detach and remove soil by its kinetic energy.^[7] In most situations, erosion by concentrated flow is the main

Fig. 1 Detachment and transport processes associated with variations in raindrop and flow energies. Line e_c : critical raindrop energy to cause erosion. Line A: raindrop energy prior to flow (this often increases slightly with time, as a soil crust develops). Line B: raindrop energy when flow occurs (increasing with time, as more drop energy is used to penetrate the deepening flow). $\omega_{c(\text{loose})}$: critical stream power for transporting loose material. $\omega_{c(\text{bound})}$: critical stream power for detaching soil from surface of soil matrix. RD-ST: raindrop detachment, splash transport. RD-RIFT: raindrop detachment, raindrop induced flow transport. RD-FT: raindrop detachment, flow transport. FD-FT: flow detachment, flow transport.

agent of erosion by water. The flow-dominated erosional channels are separated by interrill areas,^[8] where the dominant processes are rainsplash and diffuse overland flow; however, boundaries between rill and interrill areas are both ill-defined and constantly shifting.

In some circumstances, subsurface flow may be important in determining where channel erosion will begin and develop (e.g., at the base of slopes^[9] and in areas of very deep soils such as tropical saprolites^[10]). Meltwater from thawing snow operates in a broadly similar way to rain-derived overland flow,^[11] detaching and transporting unfrozen soil in areas of concentrated flow; however, snowmelt erosion is less well studied and less well understood.

As erosional channels increase in size (i.e., become large rills and gullies),^[12] processes such as the gravitational collapse of channel walls and heads increase in importance.^[13] Runoff and sediment from rills and gullies may be moved into ditches, stream, and rivers and so transported well away from the point of origin. However, sediment may also be deposited within the rill or gully or beyond the rill or gully's confines in a depositional fan, at locations where the gradient slackens. Here it may be stored for a variable period of time,^[14] possibly being reworked by tillage activity until a subsequent erosion event is of sufficient size to

Fig. 2 Impacts of erosion by water at the microscale: overland flow between millimeter-scale soil aggregates. The finger is pointing at an area where concentrated flow is just beginning to incise a microrill.

re-erode the stored sediment. It may then be redeposited further downstream or make its way into a permanent watercourse and thence to lake or ocean.

EROSION BY WATER: SPATIAL AND TEMPORAL SCALE

Water erosion's complex hierarchy of subprocesses (Fig. 1) means that erosion by water operates (and is studied) over a wide range of spatial scales.^[15] Rainsplash redistribution and the initiation of microrills and rills occur at a scale of millimeters (Fig. 2). Rill erosion on agricultural hillslopes operates at a scale of meters to tens of meters (Fig. 3), while gully erosion can occur on a scale of hundreds of meters or even kilometers. The off-site impacts of erosion can affect very large areas, sometimes hundreds or even thousands of square kilometers (Fig. 4)

At every spatial scale, however, erosion is highly patchy. Even in areas of severe erosion, rates of soil loss can vary greatly from point to point on the landscape as the vagaries of topography and land use concentrate erosive flows on a wide range of spatial scales.^[16] Obvious erosion in one field can be found side by side with virtually untouched areas, and within an eroded field, the severity of erosion can vary markedly.

Erosion by water is often also variable across a range of temporal scales. Soil loss from water erosion occurs both incrementally, as a result of many small rainfall events, and more dramatically, as a result of large but relatively rare storms. Dramatic erosion events can produce large gullies and create flooding and property damage, which hits the news headlines. However, a significant proportion of total soil loss may be due to small but frequent erosion events, which nonetheless have a notable cumulative impact.^[17]

THE GLOBAL PROBLEM OF EROSION BY WATER

While soil erosion by water has been occurring naturally for some 450 million years (since the first land plants formed the first soil), accelerated erosion is of much more existing origin. Yet on a human timescale, accelerated erosion is old. There is considerable archaeological evidence from many parts of the world that accelerated erosion by water is often associated with early agriculture.^[18,19] Water erosion's association with unwise agricultural practices was first noted within a scientific context during the second and third decades of the 20th century by pioneers of soil conservation such as Hugh Hammond Bennett in the United States, and subsequently by workers in other parts of the globe. During the period of colonialism, the imposed adoption of European agricultural methods frequently led to accelerated erosion in developing countries, a problem which continues.^[20,21] During the last few decades of the 20th century, a move toward intensive agricultural technologies which leave the soil bare during times of heavy rainfall meant that previously problem-free areas of the world,

Fig. 4 Impacts of erosion by water at the global scale: a sediment plume covering tens of thousands of square kilometers at the mouth of the Yellow River, China. This results from erosion by water on the Chinese Loess Plateau.

such as northwest Europe, began to experience notable increases in water erosion.^[22]

Despite the global nature of the problem of erosion by water, yet we do not have good information regarding the global extent of erosion by water.^[23,24] Data on the severity of erosion are also often limited.^[25]

IMPACTS OF EROSION BY WATER

Impacts of erosion by water can be categorized into on-site (i.e., affecting only the place where the erosion occurs) and off-site (i.e., affecting locations other than that at which the erosion occurs) problems.

Erosion's removal of the upper horizons of the soil results in a reduction in soil quality,^[26] i.e., a diminution of the soil's suitability for agriculture or other vegetation. This is because the eroded upper horizons tend to be the most nutrient rich. Also, because the finest constituents of eroded soil tends to be transported furthest, eroded soils become preferentially depleted of their finer fraction over time; this often reduces their water-holding capacity.^[26] In other words, "erosion removes the cream of the soil."

Increased use of artificial fertilizers may to an extent, and for a time, compensate for erosion-induced loss of soil quality where economic circumstances are favorable. However, this is not usually feasible in developing countries.^[20,21] Loss of soil quality is a long-term problem; globally, it is water erosion's most serious impact.^[27,28]

Movement of sediment and associated agricultural pollutants into watercourses is the major off-site impact resulting from erosion. This leads to silting-up of dams, disruption of the ecosystems of lakes, and contamination of drinking water.^[22] Rates of erosion do not have to be high for significant quantities of agricultural pollutants to be transported off-site.^[29] This is a shorter term impact than loss of soil quality; in the more affluent areas of the world, it can be the main driver for soil conservation policy initiatives.^[24] A more minor off-site effect can occur in situations where eroded soil has a decreased capacity to absorb water; increased runoff may lead to downstream flooding and local damage to property.^[30]

Water Erosion: Empirical Models

John M. Laflen

(Retired), U.S. Department of Agriculture—Agricultural Research Service
(USDA-ARS), Buffalo Center, Iowa, U.S.A.

Abstract

Empirical models of soil erosion by water are used to determine the extent of soil erosion, to identify areas needing soil erosion control measures, to select appropriate practices to minimize damages resulting from soil erosion, and to estimate downstream delivery of sediment and other materials. Examples of damages might include reduced productivity, exposure of landfill materials, obstacles to farming, living plant damages, increased maintenance of locks and dams, reduced reservoir capacity, reduced aquatic habitat, deposited nuclear materials, and increased eutrophication of surface waters.

INTRODUCTION

An empirical model is a representation of data.^[1] Although the models described here were developed based on relationships from data, and while these relationships are explainable to a certain extent based on our understanding of the erosion process, they came from data. The models described do not include simulation models, even those that might include empirical components, nor the application of empirical models in Geographical Information Systems.

EMPIRICAL EROSION MODEL DEVELOPMENT

Early erosion research literature describes the effect of various factors—climatic, topographic, soil, management and conservation practices, on soil erosion, and empirical models include most of these factors. Early models were relatively simple relationships with factor values generally determined based on a limited set of experimental observations and involving only a few factors. As the science progressed, the complexity increased, with relationships of factor values to factor characteristics being developed based on experimental data.

One of the early developments was establishment of erosion plots at numerous locations in the United States. These plots provided an immense data set that is used for evaluating soil erosion and hydrologic models. Over 10,000 plot years of data were collected on these plots.^[2] Additionally, many plots were located on experimental farms that contained small watersheds on which conservation practices were installed, monitored, and evaluated. These experimental areas provided the necessary data for developing the relationships in water erosion empirical models.

Erosion plots have also been established in other regions of the world. Hudson^[3] described field experiments involving erosion plots in Rhodesia. Erosion plots can be found on every continent (except Antarctica) and are frequently used to evaluate the applicability of empirical and non-empirical erosion models to specific regions and to develop appropriate factor values for practices common to those regions.

The development of empirical models has been a classic example of the operation of science and its application to solving real world problems. The steady progression of science is illustrated in [Table 1](#) where the steps in development of the U.S. empirical erosion modeling are given chronologically. The work initiated with Zingg continues, each step built on top of earlier work. Meyer^[12] gives an excellent review of the development of the Universal Soil Loss Equation (USLE) in the United States.

EMPIRICAL MODELS

Universal Soil Loss Equation

The USLE is written as

$$A = RKLSCP \quad (1)$$

where, A is soil loss per unit area (units depend on units used for R and K); R is the rainfall and runoff factor, the number of rainfall erosion index units, plus factors for runoff from snowmelt or applied water. K is the soil erodibility factor, the soil loss rate per erosion index unit on a plot 72.6 ft long of uniform 9% slope maintained in a clean tilled fallow. L is the slope length factor, the ratio of soil loss for a given slope length to a 72.6 ft long slope. S is the slope steepness factor, the ratio of soil loss for

Table 1 Evolution of U.S. empirical water erosion models.

Reference	Soil loss	Coefficient or rainfall factor	Soil erodibility factor	Length—slope factor	Cropping management factor	Conservation practice factor
Zingg ^[4]	A	C'	$L^{0.6}S^{1.4}$

A, soil loss (ton/acre); A', soil loss (in./yr); A*, sediment delivery (ton/yr); P_{30} , maximum precipitation amount (in.) falling in 30 minutes in a storm; Q, storm runoff volume (acre-ft); q_p , peak runoff rate (cubic ft per sec); Q_0 , storm runoff volume (in.); q_0 , peak runoff rate (in. per hr); E, storm rainfall energy (hundreds of ft-ton per acre); I_{30} , maximum rainfall intensity in a 30-minute period within a storm (in. per hr); K', K', K, soil erodibility factors; L, slope length (ft); S, slope (%); Θ , slope angle (°); m, exponent on length term; values depend on slope or slope and rill/interrill ratio; a, b, coefficients in function making up slope term; values depend on slope; C', C', C''', coefficients; C*, egetal cover factor; C, cropping and management factor (before 1978) and cover and management factor (after 1978); P, conservation practice factor.

a given slope to soil loss from a 9% slope. C is the cover and management factor, the ratio of soil loss for a given land use and management to soil loss from a continuous clean tilled fallow. P is the support practice factor, the ratio of soil loss with a support practice, such as contouring, terracing, or stripcropping, to soil loss for up and down the slope.

Much more detail on factor values, and assistance in computing these values can be found in Wischmeier and Smith.^[2]

The USLE was the culmination of over two decades of work in developing a national model of soil erosion by water. As shown in Table 1, the form and factors were long established before the USLE was developed. The defining scientific finding in the development of the USLE was that of Wischmeier and Smith^[13] when they isolated a single rainfall variable that could be used over the United States to model soil erosion from rainstorms. This allowed the application of factor values in one region to be used in another region. Climatic databases were developed for the entire United States, and tables and charts were published to allow use of the USLE for most U.S. conditions.^[2,8,14] The USLE technology was the water erosion model of choice over much of the world through the 20th century. It is being replaced by Revised Universal Soil Loss Equation (RUSLE) in the United States.^[11,15]

While the USLE is a good predictor of average annual erosion, it is a poor predictor of individual storm soil erosion because it does not contain variables associated with the hydrologic condition of the soil at the time the storm occurs. Additionally, the USLE does not consider deposition on a field, and does not predict sediment yield, a needed estimate for many applications.

The USLE's area of application is from the top of a hillslope (or divide) to where deposition begins, or runoff enters a channel.

Modified Universal Soil Loss Equation (MUSLE)

MUSLE is written as

$$A^* = 95(Qq_p)^{0.56} KLSCP \quad (2)$$

where A* is sediment delivery, Q is total volume of runoff, and q_p is peak rate of surface runoff, and K, L, S, C, and P are the same as for the USLE.

MUSLE was developed to predict individual storm sediment yield. A major shortcoming of the USLE for many applications was that while it estimated soil erosion, it did not predict sediment yield, and it was a poor predictor of individual storm soil erosion. Williams et al.^[16] determined that for individual storms, sediment concentration for five small watersheds near Riesel, Texas, was highly correlated with the ratio of peak runoff rate per square mile to total volume of runoff. Williams and Berndt^[17] applied the USLE to average annual sediment yield prediction for the same five small watersheds using a delivery ratio based on watershed characteristics. They weighted the various factors in the USLE (except for the rainfall factor) based on drainage area of the various factor values, channel lengths, channel slopes, and cultivated area.

Williams^[9] examined three forms of a runoff factor and determined that the runoff factor $95(Qq_p)^{0.56}$ (with Q, the volume of runoff given in acre-feet, and q_p , the peak flow rate given in cubic feet per seconds) was the best form for estimating individual storm sediment yield from small

watersheds. In the analysis, he used the procedures of weighting the USLE factors pioneered in 1972. The 18 watersheds ranged in size from 2.7 to 4380 acres. Two watersheds were located at Hastings, Nebraska, and the remainder were located at Riesel, Texas, and included the five small watersheds used in earlier analyses.

MUSLE requires inputs—storm volume of runoff and peak rate of runoff, not used in the USLE. This information can be generated by simulation models or it can be estimated for design storms.

MUSLE continues to be heavily used in various modeling activities. It is an option in the EPIC model^[18] for computing sediment yield. While MUSLE is widely used, there are few publications that detail the accuracy of MUSLE, outside of the original work performed by Williams in its development.

ONSTAD-FOSTER (OF) MODIFICATION OF THE USLE

The OF modification of the USLE is written as

$$A = (0.5R + 15Q_o q_o^{0.33}) KLSCP \quad (3)$$

where A, R, K, L, S, C, and P are the same as for the USLE, and Q_o is runoff volume in inches and q_o is peak flow rate in inches per hour.

Foster et al.,^[19] using basic erosion principles, derived a soil loss equation that included a runoff parameter and a rainfall parameter to replace the rainfall factor in the USLE. This factor was $0.5R + 15Q_o q_o^{0.33}$. Onstad and Foster^[10] found good results when the factor was tested using watershed data from Ohio and Iowa.

Again, as for MUSLE, hydrologic information must be available to estimate peak rate and total volume of storm runoff. A major difference between MUSLE and OF are the approaches used in developing the equations—MUSLE variables were selected and tested, while OF variables were determined based on analysis of fundamental erosion processes. Hence, the difference in forms. It has never been established that one is a superior predictor to the other.

OF has received limited use, although it is also an option for use in some modeling activities, including the EPIC model.

Soil Loss Estimation Model for Southern Africa (SLEMSA)

Elwell^[20] introduced SLEMSA as a reliable management tool developed from limited resources. The development team evaluated the USLE for adoption in southern Africa but were concerned about adopting factor values developed in America.^[21] Additionally, there was considerable concern about differences in farming practices. They felt that

they did not have the resources to implement the USLE, and a simpler approach was needed.

SLEMSA is written as

$$Z = KCX \quad (4)$$

where Z is mean annual soil loss, K is mean annual soil loss from a standard field plot 30 m × 10 m at 4.5% slope for a soil of known erodibility under a weed-free bare fallow, C is the ratio of soil lost from a cropped plot to that lost from bare fallow land, and X is the ratio of soil lost from a plot length L and slope percent S to that lost from the standard plot.

K values are computed as

$$\ln K = \ln E + a \quad (5)$$

where E is seasonal rainfall energy, and a and b are given by

$$a = 2.884 - 8.1209 F \quad (6)$$

$$b = 0.4681 + 0.7663 F \quad (7)$$

where F is soil erodibility. Based on soil texture, F is assigned a value between 4 (light textured, or sandy soil) and 6 (heavy textured, or clay soil). Additional adjustments are made based on hydrologic characteristics of the soil, tillage, soil structure, and crusting, giving a range of F values from 1 to 9.

C is computed as $C = e^{(-0.06i)}$ when $i < 50\%$, and as $C = (2.3 - 0.01i)/30$ when $i \geq 50\%$, where i is the percentage rainfall energy intercepted by the crop (used crop cover %).

X is computed as

$$X = (l)^{1/2} (0.76 + 0.53s + 0.076s^2) / 25.65 \quad (8)$$

This is derived from the USLE LS factor in use in the 1970's. The equation above converted the USLE LS factor to the metric system, and adjusted it to a 4.5%, 30m long slope. The variables l and s are length (m) and slope (%).

The USLE and SLEMSA are very similar in many respects. The major differences are in the climate variables and the cropping management approaches. The USLE climate factor contains both rainfall energy and rainfall intensity, whereas SLEMSA contains only rainfall energy. The USLE C value incorporates both tillage and cropping, while the C value for SLEMSA is a function of the interception of rainfall energy by crops. However, SLEMSA does capture some of the tillage component in the F value.

ABAG (German USLE)

Auerswald^[22] described the application of the USLE in Germany. Experimentally, most of the USLE factors were validated, and few if any modifications were needed to apply it under German conditions. One modification was that soils highly enriched in potassium were found to be

more erodible than expected, based on the soil erodibility nomogram of Wischmeier et al.^[23]

While no modification of the USLE was found necessary, ABAG factors were necessary for German conditions, specifically the R and C factors. Schwertmann et al.^[24] published a book for extension workers in Germany detailing the use of the USLE in Germany.

SOIL LOSS

Rosewell and Edwards^[25] developed a computer program that used the USLE approach to estimate average annual soil losses and to give recommendations on ways to reduce soil loss through changes in land and crop management practices. SOILOSS was developed for use in New South Wales, Australia. It used a slightly different equation for computing rainfall energy than that used in the USLE. It also used both the USLE nomogram for soil erodibility, plus experimentally derived values for NSW. In a later revision,^[26] Rosewell adopted LS values from RUSLE. From the earliest version of SOILOSS, the subfactor approach of Laflen et al.^[27] that was implemented in RUSLE was used to estimate the C value. It also contained P value estimates similar to those in the USLE, but some were from experimental work in NSW. It also included a benefit from sediment deposited in bank (terrace) channels.

Keats and Rosewell developed a SOILOSS user guide^[28] for high school students. It included the program, an introduction to the USLE, and complete parameterization for most Australian conditions. It included worksheets and examples.

In a number of ways, SOILOSS could be considered an early RUSLE, using much of the science and approaches that were eventually used in RUSLE. It was also developed in the time frame where RUSLE was developed.

Revised Universal Soil Loss Equation

RUSLE^[11] maintains the form of the USLE in terms of the factors. But, since it is operated on a computer, many improvements in computations, particularly those including interactions, have been incorporated. Major improvements in the revised USLE include improved R value map for the United States, time variation in soil erodibility, improved LS factor that incorporates modern science, a subfactor approach for computing the cover and management factor, and P values based on modeling analyses that include storm severity, ridge height, drainage, and off-grade contouring.

RUSLE has been implemented for use in erosion prediction by the Natural Resource Conservation Service in the United States. It is also used in several simulation models. RUSLE development continues, with

improvements in science, ease of use, supporting databases, and applications related to sediment deposition and delivery.

CONCLUSION

Empirical erosion modeling has been applied on much of the earth's land surface. The approaches have almost exclusively been to quantify factors that influence soil erosion, and then to combine these factors, usually as products of the factors. The development of empirical models has clearly been an evolutionary process, and almost all models owe all or much of their technology to the USLE.

Abstract

Simulation models are among the best tools available for analyzing soil erosion and conservation management. Models can project the consequences of alternative management, conservation planning, or policy-level activities and substantially reduce the cost of managing soil and water resources. Numerous models have been developed to estimate soil erosion and the impact of land management on erosion. Equations have been integrated into comprehensive hybrid models that directly simulate hydrology, plant growth, nutrient cycling, and land management impacts on soil erosion.

INTRODUCTION

Each year, soil erosion causes billions of dollars of damage in the world.^[1] Simulation models are among the best tools available for analyzing soil erosion and conservation management. Models can project the consequences of alternative management, conservation planning, or policy-level activities and substantially reduce the cost of managing soil and water resources. Numerous models have been developed to estimate soil erosion and the impact of land management on erosion. Early models such as the universal soil loss equation (USLE)^[2] were empirical and predicted average annual erosion rates using simple nomograph procedures. The USLE and its subsequent improvements have been modified and enhanced.^[3,4] These equations have been integrated into comprehensive hybrid models that directly simulate hydrology, plant growth, nutrient cycling, and land management impacts on soil erosion. Then, the models use predicted soil erosion to estimate nutrient, pesticide, and bacteria transport; change in soil productivity; and carbon dynamics.

EROSION EQUATIONS

The USLE has been used throughout the world to estimate average annual sheet and rill erosion. Several improved forms of the USLE have been developed that include the Onstad–Foster equation^[4] and modified universal soil loss equation (MUSLE).^[3] The equations are identical except for their energy components. The USLE strictly depends on rainfall as an indicator of erosive energy. The MUSLE and

its variations use only runoff variables to simulate erosion and sediment yield. Runoff variables increase the prediction accuracy, eliminate the need for a delivery ratio, and enable the equation to give single-storm estimates of sediment yields. The USLE gives only average annual estimates. The Onstad–Foster equation contains a combination of the USLE and MUSLE energy factors. The empirical erosion model equations are of the following form:

$$Y = \chi(K)(C)(P)(LS) \quad (1)$$

$$\chi = EI \quad \text{for USLE} \quad (2)$$

$$\chi = 0.646EI + 0.45(Qq_p)^{0.33} \quad \text{for Onstad–Foster} \quad (3)$$

$$\chi = 1.586(Qq_p)^{0.56}A^{0.12} \quad \text{for MUSLE} \quad (4)$$

where Y is the sediment yield (t/ha), K is the soil erodibility factor, C is the crop management factor, P is the erosion control practice fact, LS is the slope length and steepness factor, Q is the runoff volume (mm), q_p is the peak runoff rate (mm/h), and A is the watershed area (ha).

COMPREHENSIVE HYBRID MODELS

Numerous hybrid models have been developed including Revised USLE (RUSLE),^[5] groundwater loading effects of agricultural management systems (GLEAMS),^[6] and agricultural nonpoint source pollution model (AGNPS).^[7] Three comprehensive hybrid models with varying spatial

scales will be discussed in more detail: field scale—environmental policy impact calculator (EPIC), small watershed scale—agricultural policy/environmental extender (APEX), and river basin scale—soil and water assessment tool (SWAT). All three models use modified versions of USLE for erosion and link with components for plant growth, hydrology, and management. APEX and SWAT also include components for channel sediment routing and pond and reservoir deposition.

The EPIC model^[8] was developed in the early 1980s to assess the effect of erosion on productivity. The model has since been expanded and refined to allow the simulation of many processes important in agricultural management.^[9] EPIC is a continuous simulation model (daily time step) that can be used to determine the effect of management strategies on water quality. The drainage area considered by EPIC is generally a field-sized area, up to 100 ha, where weather, soils, and management systems are assumed to be homogeneous. The major components in EPIC are weather simulation, hydrology, erosion, nutrient cycling, pesticide fate, plant growth, soil temperature, tillage, economics, and plant environment control. EPIC can be used to compare management systems and their effects on sediment nitrogen, phosphorus, and pesticides. The management operations that can be simulated are crop rotations, tillage operations, irrigation scheduling, drainage, furrow diking, liming, grazing, manure handling, and nutrient and pesticide application rates and timing.

The APEX model^[10] was developed to extend the EPIC model capabilities to whole farms and small watersheds. In addition to the EPIC functions, APEX has components for routing water, sediment, nutrients, and pesticides across complex landscapes and channel systems to the watershed outlet. A watershed can be subdivided to assure that each subarea is relatively homogeneous in terms of soil, land use, management, etc. The routing mechanisms provide for the evaluation of interactions between subareas involving surface run-on, return flow, sediment deposition and degradation, and nutrient transport. Water quality in terms of nitrogen (ammonium, nitrate, and organic), phosphorus (soluble and adsorbed/mineral and organic), and pesticide concentrations may be estimated for each subarea and at the watershed outlet. APEX is limited in watershed size because of the detailed crop management system and because daily rainfall is uniformly distributed over the entire watershed.

SWAT^[11] is a complex, conceptual model with spatially explicit parameterization. It is a continuous time model that operates on a daily time step. The objective in model development was to predict the impact of management on water, sediment, and agricultural chemical yields in ungauged basins. To meet this objective, the model is physically based (as calibration is not possible on ungauged basins) on readily available inputs, is computationally efficient to operate on large watersheds and in a reasonable time, and is capable of continuous simulation over long time periods necessary for computing the effects of management changes. Major model

components include weather, hydrology, erosion/sedimentation, soil temperature, plant growth, nutrients, pesticides, groundwater flow, land management, stream routing, and pond/reservoir routing. SWAT allows a large basin to be subdivided into grid cells or subwatersheds and allows point source inputs and reservoirs to be included in the drainage network. Basins with size ranging from 100 to 100,000 km² have been simulated.^[12] Geographic information system (GIS) interfaces have been developed using GRASS and ArcView to automate model input development and spatially display model outputs.^[13]

MODEL COMPONENTS THAT INTERACT WITH EROSION EQUATIONS

Fig. 1 shows major model components and their interaction with other components and management. The major process components that influence erosion are hydrology, plant growth, residue decay, and management (rotations, tillage, irrigation, fertilizer, and manure).

Hydrology

The primary driver of soil erosion by water is surface water runoff that is caused by rainfall, snowmelt, and irrigation. To simulate surface runoff accurately, an estimate of soil moisture at the start of the runoff event is critical. For continuous time models, the components of the soil water balance must be simulated between events. The main components of the soil water balance are canopy storage, surface runoff, infiltration, snow fall and melt, evapotranspiration (ET), percolation, and lateral soil flow (Fig. 2). The hybrid models discussed here use a daily time step for most water balance processes with the option of subdaily time step for the rainfall/runoff process. Hybrid models using empirical erosion models such as MUSLE and Onstad–Foster require peak rate and total runoff volume from the hydrology routines.

Plant Growth

Simulation of plant growth is crucial for accurate prediction of soil erosion. Plant growth impacts water extraction from the soil (ET), canopy and residue cover, and nutrient uptake. In most climates, the largest component of the water balance is ET. ET indirectly affects erosion by modifying soil moisture between rainfall events and thus impacting soil erosion. Canopy and residue cover have direct impact on the erosion equations. For the hybrid models, a relationship between cover (canopy and residue) and the USLE C-factor was developed.^[8]

Residue Decay

Decay of plant residue (including standing, flat, buried, and roots) reduces the amount of residue protecting the soil surface from erosion. Decay is normally simulated as a function of temperature; soil moisture; and soil carbon,

Fig. 1 Major hybrid model components and their interactions with management practices.

nitrogen and phosphorus contents. The hybrid models simulate nutrient cycling and track nutrient pools in the soil and nutrient concentrations in the plants and residue. The decay rates can then be calculated as a function of the soil C/N and C/P ratios and the composition of plant residue.

Management

Plant growth management is simulated by most comprehensive models. Crop rotations, planting and harvest dates, the length of growing season, cuttings, and grazing all impact the water balance and the amount of canopy and ground cover.

Tillage

Tillage operations remove plant residue from the soil surface (standing and flat) and incorporate residue into the soil, reducing cover. Tillage also mixes nutrients and changes soil properties such as erodibility, bulk density, and hydraulic conductivity.

Irrigation

Surface irrigation often produces surface runoff and erosion. Irrigation also affects the soil water balance by increasing soil moisture and thus increasing surface runoff and erosion during rainfall events.

Fertilizer and manure management

Application of manure and commercial fertilizers influences soil carbon, nitrogen, and phosphorus and thus influences residue decomposition. Increased fertilizer application can increase plant growth and potentially increase canopy and residue cover. Soil properties such as erodibility and bulk density are altered by fertilizer and manure applications.

MODEL APPLICATIONS

Applications of hybrid soil erosion models include farm planning, erosion productivity,^[14] sustainable farming systems, carbon sequestrations,^[15] climate change,^[16] and total maximum daily loads (TMDLs).

EPIC Applications

1985 RCA appraisal

The USDA used EPIC to simulate the soil-climate-plant management processes in agricultural production and to estimate the impact of soil erosion on resource productivity and fertilizer requirements for the 1985 Resources Conservation Act appraisal.^[14] EPIC results showed that

Fig. 2 Major components of the hydrologic balance in hybrid models.

if cropping patterns and the mix of management, tillage, and conservation practices continued for 100 years, sheet and rill erosion will exceed soil loss tolerance on 127 million acres. Annual fertility requirements are estimated to increase by 798 and 672 million pounds of nitrogen and phosphate, respectively.

Environmental protection agency (EPA) nutrient movement study

EPA used EPIC to examine the impacts of tillage on nitrogen and phosphorus movement. Four tillage strategies were examined using 100-year EPIC simulations at 100 sites in

Illinois. Simulated crop yields closely corresponded to expected yields. No till corn/soybean rotations were found to reduce sediment-attached nitrogen and phosphorus in runoff relative to conventional till continuous corn.^[17]

APEX Applications

Animal waste recycling

The APEX model has been used to study animal water disposal systems in the Upper North Bosque watershed in Texas. Various forage production systems and soils were simulated to illustrate the interactions among crops, manure recycling, and nutrient losses.

Buffer analysis

APEX was used to evaluate buffer grass strip efficiency under a variety of soils, climate, slope, and management across the United States. Relationships of buffer trapping efficiency of sediment and nutrients were developed for use in regional buffer analysis studies and for use in watershed models.^[18]

SWAT Applications

Hydrologic unit model of the United States

The Natural Resources Conservation Service (NRCS) used the SWAT model for the 1997 Resource Conservation Assessment. The model was linked to national economic models and used for national policy planning of water supply and quantity of the 18 major river basins of the United States. GISs were utilized to integrate SWAT with national soils, land use, and elevation databases.^[19]

TMDL analysis

There are approximately 15,000 water bodies in the United States identified by EPA as impaired for various uses. For each of these, states must estimate the severity of the problem (develop a TMDL) and determine potential solutions. SWAT has been selected by EPA for use in TMDL analysis and is being used to determine the impact of proposed management practices on attaining water quality standards.^[20]

Water Erosion: Modeling

Calvin W. Rose

Faculty of Environmental Sciences, Griffith University, Nathan Campus, Nathan, Queensland, Australia

Abstract

An outline is given to the development from earlier statistically based models of water-driven soil erosion to models designed to represent the physical processes involved. Examples of dynamic and steady-rate process models are also given.

INTRODUCTION

Modeling soil erosion by water was initially developed in the context of agricultural productivity and land degradation.^[1–4] Modeling was subsequently stimulated by off-site concerns for the water quality of streams, lakes, and oceans.^[5,6] Soil erosion by water is also recognized as one process in the (most) descriptive long-term, land-forming models of geomorphologists and geographers,^[7,8] which include mass movement and other forms of erosion. The concern that soil erosion might ultimately expose buried contaminants has encouraged modeling as a possible landscape change over thousands of years.^[9,10]

Early erosion models used statistical techniques to summarize large bodies of data, giving the effect of environmental and agricultural management factors on net soil loss from agricultural plots.^[1,2] The Revised Universal Soil Loss Equation (RUSLE),^[11] a familiar example, developed from the USLE summarizes erosion experiments in U.S. field plots.^[1] RUSLE allows prediction of annual expected net soil loss from a plot of uniform slope throughout an entire crop rotation, using databases for climate, vegetation, and field-management operations that are available for the United States. The annual soil loss per unit area, A , is given by as follows:

$$A = RKLSCP$$

where R is a rainfall-runoff factor, K is soil erodibility factor, L is slope length factor, S is slope steepness factor, C is cover management factor, and P is support practices factor.

Later, soil erosion modeling developments primarily use deterministic models, which seek to represent the physical, hydrological, and sediment transport–deposition processes involved.

SOIL EROSION PROCESSES

Water-induced soil erosion involves downslope flow of water with a sediment concentration that depends on the net

balance of two rapid but opposing types of processes.^[12–14] Sediment removed from the soil surface adds to the sediment concentration, a process countered by deposition, which continuously returns sediment to the soil surface at a rate depending predominantly on the distribution of size and density of the sediment.^[13] The rate of soil removal depends on an interaction of rainfall and overland-flow characteristics with soil strength-related properties, which can be affected by subsurface hydrology.^[15–21]

The impact of raindrop on unprotected soil is commonly the initial soil-removal mechanism.^[13,22] However, when an excess of rainfall over infiltration rate occurs, the resulting overland flow both transports sediment and exerts a shear stress on the soil, τ . This shear stress arises chiefly from turbulence,^[15,17,18] and its rate of action is called the stream power, Ω

$$\Omega = \tau V$$

where V is the velocity of flow.

For cultivated soil, overland flow-driven erosion processes usually become dominant over rainfall-driven processes when Ω exceeds approximately 0.2 W m^{-2} .^[23]

DYNAMIC STOCHASTIC AND DETERMINISTIC MODELS OF SOIL EROSION

The rates of sediment removal from, and return to, the soil surface in deposition can be described stochastically.^[24] The probability density of resting on the soil surface is a function of time alone, but the probability to describe motion involves both space and time. This leads to two simultaneous partial differential equations, one related to the deposited or stationary mass and the second to sediment in motion.^[24] These two equations are formally identical with the two partial differential equations derived using deterministic mass-conservation considerations.^[16,24]

Fig. 1 gives a deterministic representation of rainfall-driven erosion, recognizing that soil consists of a range of

Fig. 1 Forrester-style flow diagram describing the interaction of rainfall detachment and redetachment processes among the original soil, the layer formed by deposition, and the sediment flux. The water layer with sediment concentration c_i (for size class i) and the deposited layer of mass per unit area m_{di} are shown artificially elevated for clarity. Rates of processes exchanging sediment are shown by valve symbols.

Source: From Hairsine & Rose.^[16]

particle sizes. For a typical size class (i), e_i is the rate of detachment from the original soil matrix. Deposition at rate (d_i) from sediment in the overland flow forms a deposited layer of mass per unit area (m_{di}), from which sediment is redetached at rate e_{di} . Let c_i denotes the concentration of sediment in i at any time (t) in depth of water (D), with volumetric flow per unit width (q) in the x direction. Then mass conservation of sediment of i flowing over the soil surface requires that^[16,25]

$$\frac{\partial}{\partial t}(Dc_i) + \frac{\partial}{\partial x}(qc_i) = e_i + e_{di} - d_i \quad (1)$$

Mass conservation of sediment in the deposited layer (Fig. 1) requires that

$$\frac{\partial}{\partial t}(m_{di}) = d_i - e_{di} \quad (2)$$

Solution of Eqs. 1 and 2 (or corresponding equations when flow-driven processes are also important) involves numerical or approximate analytical methods.^[25–28] A major purpose of such models is to test the physical understanding of basic dynamic soil erosion and deposition processes. Dynamic models also help in choosing approximations for simpler steady-rate models, which are more suitable for application in field-predictive applications. Use of steady-rate models avoids the need to solve partial differential equations in space and time.

Especially at long-time scales and catchment space scales, there is a change in land surface elevation that results from net erosion or net deposition, an issue ignored

in equations such as Eqs. 1 and 2, but crucial in seeking to describe landscape evolution.^[7,8] A quantitative general model of channel network growth and hillslope evolution has been developed whose output resembles many observed landscape features.^[29–32] In this model, surface denudation is represented as the sum of fluvial transport processes, dependent on discharge and slope, and a slower analog of diffusive processes dependent on slope alone. Digital terrain modeling is used to determine drainage areas, and the landform is adjusted through time in response to erosion processes.

Three physically based steady-rate models that have received significant application in land use contexts are outlined below.

STEADY-RATE MODELS OF WATER EROSION

Water Erosion Prediction Project

Developed by the U.S. Department of Agriculture, the hillslope version of Water Erosion Prediction Project (WEPP) is a comprehensive, continuous simulation model that draws on U.S. databases describing climate, soils, tillage, and crop parameters.^[33,34] Runoff is generated from rainfall input using an infiltration equation.^[34] The peak predicted runoff rate is the steady-rate value assumed for the erosion event.

Sediment sourced from the inter-rill area is delivered to rills, and net erosion within rills can add to transported sediment. If predicted total sediment transport exceeds the maximum transport limit, a separate equation acknowledges that net deposition will occur, representing a mass conservation of transported sediment. A flow chart of the WEPP profile model is shown in Fig. 2.

U.S. databases provide the 64 parameters needed to run the model. However, experience outside the United States indicates that infiltration and erodibility parameters, in particular, must be obtained from in-country experiments if predictions of soil and water loss are to be of useful accuracy.^[35] More versions of the WEPP model allow for simulation of small watersheds.^[36]

Griffith University Erosion System Template

Program Griffith University Erosion System Template (GUEST)^[37] is based on physical theory.^[13,16–18,38] The simpler of two options in GUEST defines an empirical erodibility parameter β and uses the mean velocity of sediment settling as a soil characteristic.^[13] GUEST also addresses rilling in a physical manner.^[13,38] If total runoff amount is alone measured, an effective runoff rate for an erosion event can be calculated from rainfall rate.^[39,40] If β has been previously determined or can be estimated, then the program can be used to predict soil loss.

Fig. 2 Flow chart illustrating the components of the hillslope profile version of WEPP.

Source: From Lane & Nearing.^[34]

GUEST assumes that a constant fraction of the excess stream power $\Omega - \Omega_0$, where Ω_0 is a threshold value, is used in flow-driven erosion.^[13,18] The maximum sediment concentration or transport limit (c_t) is derived theoretically.^[13,18] The erodibility parameter β is given by

$$\beta = (\ln \bar{c}) / (\ln \bar{c}_t) \quad (3)$$

where $\bar{c}$ is the average sediment concentration and $\bar{c}_t$ is the average value of c_t during an erosion event. How the relation between $\bar{c}$ and Ω is controlled by the value of β is shown in Fig. 3.

European Soil Erosion Model

European soil erosion model (EUROSEM)^[41,42] describes erosion for single events on single-slope segments (as does GUEST), uses an experimentally based relationship for the transport limit,^[43] and is linked to the KINEROS hydrologic model.^[44] The numerical-solution procedure in KINEROS provides the basis for sediment discharge calculation. Net deposition occurs if the calculated sediment concentration exceeds the transport limit. Sediment removed by rainfall impact is delivered to rills, which transport the sediment (as in WEPP).

EUROSEM represents canopy protection against rainfall impact, adding drop impact due to throughfall. The effect of different cultivation practices on surface water storage is also represented.

Fig. 3 The relationship between sediment concentration, c , and streampower for various values of the erodibility parameter β given in Eq. 3. For $\beta = 1$ (the upper curve), $c = c_t$, the sediment concentration at the transport limit. (After Rose, where assumed values of other parameters are given.)

CONCLUSION

Theoretically driven process-based models are available that have demonstrated their ability to interpret and guide field experimentation on soil erosion driven by rainfall and runoff. Examples of such models are outlined, and similarities and differences between such models are noted.

Water Erosion: Process-Based Modeling

Mark A. Nearing

Watershed Research Center, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Tucson, Arizona, U.S.A.

Abstract

Soil erosion models can play a critical role in addressing problems associated with soil protection and conservation. They are used for assessment and inventory purposes when financial and time costs of obtaining useful soil erosion measurements are prohibitive. They provide assessments of both on-site loss of topsoil and off-site delivery of sediments from fields and catchments. Thus, they have value for addressing both declining soil productivity on agricultural lands and problems associated with non-point source pollution. Models are used for purposes of conservation planning, primarily for selecting the most appropriate conservation measures from a range of options for a particular field or geographical region. Models are also used with increasing frequency by governmental agencies at all levels to set regulations for erosion control practices for agriculture, construction, and forestry operations. Finally, models are used to increase and synthesize our knowledge of soil erosion and conservation science.

INTRODUCTION

Historical models of soil erosion by water have been primarily either empirically based or process based (sometimes referred to as physically based). The first models of soil erosion were empirically based. The prime example of the empirically based model is the Universal Soil Loss Equation (USLE).^[1,2] More models have been based on equations which describe the physical, biological, and/or chemical processes which cause or affect soil erosion. It is important to understand that both the process-based and the empirically based models possess a major empirical component, in the sense that the constitutive equations use parameters based on experimental data.

PROCESS-BASED MODELS

Process-based erosion models address soil erosion on a relatively fundamental level using mass balance differential equations for describing sediment continuity on a land surface. The fundamental equation for mass balance of sediment in a single direction on a hillslope profile is given as follows:

$$\partial(cq)/\partial x + \partial(ch)/\partial t + S = 0 \quad (1)$$

where c (kg/m^3) is sediment concentration, q (m^2/s) is unit discharge of runoff, h (m) is depth of flow, x (m) is distance in the direction of flow, t (s) is time, and S [$\text{kg}/(\text{m}^2 \text{s})$] is the source/sink term for sediment generation. Eq. 1 is an exact 1-D equation. It is the starting point for development of all process-based models. The differences in various erosion models are primarily: 1) whether the partial differential

with respect to time is included and 2) differing representations of the source/sink term, S . If the partial differential term with respect to time is dropped, then the equation is solved for the steady state, whereas the representation of the full partial equation represents a fully dynamic model. The source/sink term for sediment, S , is generally the greatest source of differences in soil erosion models. It is this term that may contain elements for soil detachment, transport capacity terms, and sediment deposition functions. It is through the source/sink term of the equation that empirical relationships and parameters are introduced.

One of the earliest process-based erosion models was presented by Meyer and Wischmeier.^[3] This model considered soil detachment by rain and by runoff and then compared the sediment load generated from this detachment to the sediment transport capacity of the flow. If sediment load exceeded sediment transport capacity, then deposition was calculated. The ideas from this early work were expanded and revised by Foster and Meyer^[4] and ultimately were worked into the Chemicals, Runoff, and Erosion from Agricultural Systems (CREAMS) model,^[5] which is a hybrid model in the sense that it uses process-based equations with parameters from the USLE. Experience from developing CREAMS then led to the development of the fully process-based Water Erosion Prediction Project (WEPP) model.^[6]

CONTINUOUS SIMULATION MODELS

Process-based models for soil erosion by water may be either continuous simulation or event models. Continuous simulation models predict soil erosion for series of

individual storms and have auxiliary components for updating system parameters between storms. Event models simply predict erosion for individual storm events but require the user to provide system information for each event. As such, the continuous simulation model is useful for analyzing the effects of crop management systems on erosion, whereas the event model is relatively limited in that regard.

The WEPP model is an example of a continuous simulation model. WEPP includes the following nine major components: climate, infiltration, water balance, winter process and snowmelt erosion, plant growth and residue decomposition, irrigation, surface runoff, rainfall erosion, and channel routing for watersheds.^[6] System parameters which are updated on a daily basis within the continuous simulation include soil moisture, soil density, soil resistance to erosion, plant canopy, surface residue, soil surface roughness, soil surface sealing and crusting, buried residue amounts, frozen soil layers, snow cover, and roots. All of these system parameters define the antecedent conditions for each erosion event.

The WEPP climate model has been tested for erosion and well parameterized for the United States.^[7] The infiltration component of the hillslope model is based on the Green and Ampt equation as modified by Mein and Larson,^[8] with the ponding time calculation for an unsteady rainfall.^[9] The water balance and percolation component of the profile model is based on the water balance component of Simulator for Water Resources in Rural Basins,^[10,11] with some modifications for improving the estimation of percolation and soil evaporation parameters. The plant growth component of the model simulates plant growth and residue decomposition for cropland and rangeland conditions. The residue and root decomposition model simulates the decomposition of surface residue (both standing and flat), buried residue, and roots for the annual crops specified in the WEPP User Requirements^[12] plus perennial crops of alfalfa and grasses. Surface runoff is calculated using a kinematic wave equation. Flow is partitioned into broad sheet flow for inter-rill erosion calculations and concentrated flow for rill erosion calculations. The erosion component of the model uses a steady-state sediment continuity equation that calculates the net values of detachment or deposition rates along the hillslope profile.^[13] The erosion process is divided into rill and inter-rill components where the inter-rill areas act as sediment feeds to the rills, or small channel flows. The model is applicable to hillslopes and small watersheds.

Because the model is based on all of the above-mentioned processes, and more, it is possible with a continuous simulation, process-based model to have an enormous array of possible system interactions represented in the simulations. Just to name a very few examples, slope length and steepness effects are functions of soil consolidation, surface sealing, ground residue cover, canopy cover, soil water content, crop type, and many other factors. Ground residue cover is a function of biomass production

rates, tillage implement types, residue type, soil moisture, temperature and solar radiation, previous rainfall, and many other factors. Rill erosion rates are a function of soil surface roughness, ground cover, the consolidation of soil, soil physical and chemical properties, organic matter, roots, inter-rill erosion rates, slope, and runoff rates, among other factors. The lists continue ad infinitum. These are interactions which are simply not possible to represent with an empirical model. The continuous simulation, process-based model is quite complex in this sense.

The disadvantage of the process-based model is also the complexity of the model. Data requirements are huge, and with every new datum element comes the opportunity to introduce uncertainty, as a first-order error analysis would clearly indicate. Model structure interactions are also enormous in number, and with every structural interaction comes the opportunity for error, as well. In a sense, the goal in using the process-based model is to capture the advantages of the complexity of model interactions, while gaining the accuracy and dependability associated with the simpler empirically based model. This can be done and was done with the WEPP model, using a combination of detailed sensitivity analyses and calibration of the model to the large database of natural runoff plot information used to develop the USLE. Without the tie between model and database, and without knowledge of the sensitive input variables so as to know where to focus efforts, turning a complex model such as WEPP into a useful conservation tool would not be possible. Thus, in a sense, even though WEPP routines are process-based descriptors of various components of the erosional system, ultimately the model must be empirically based on the same type of data as was used to develop the USLE, along with additional experimental data collected specifically for WEPP.

Examples of process-based event models of soil erosion by water include the European Soil Erosion Model (EUROSEM),^[14] the Hairsine and Rose model,^[15,16] and Griffith University Erosion System Template (GUEST).^[17] EUROSEM is a fully dynamic model which simulates the erosion, transport, and deposition of sediment over the land surface by inter-rill and rill processes. The model requires break-point rainfall data, ideally of one-minute resolution, as input along with a detailed description of the soils, slopes, and land cover of the watershed. The model computes the interception of rainfall by the plant cover, the generation of runoff as infiltration excess, soil detachment by raindrop impact and runoff, the transport capacity of runoff, and the deposition of sediment. EUROSEM uses the runoff generator and the water and sediment routing routines of the Kinematic Runoff and Erosion Model.^[18] The model of Hairsine and Rose^[15,16] develops the ideas presented earlier by Rose and colleagues,^[19,20] where erosion is calculated as a net balance of instantaneous processes of

sediment entrainment, deposition, and re-entrainment. The GUEST model^[17] is a practical conservation tool developed from these same concepts.

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Infiltration is the vertical downward entry of water into the soil. It is an important component of the hydrological cycle, which recharges the soil and the groundwater resources underneath. The rate of infiltration of water into soil controls the amount of water storage, runoff, and erosion of the soil. Knowledge of water infiltration into soil is essential for determining strategies of soil and water conservation and minimizing the risk of nonpoint source pollution.

INTRODUCTION

Infiltration—the entry of water into the soil—is one of the important components of the hydrological cycle (Fig. 1). It recharges the soil and the groundwater resources underneath. The rate of infiltration of water into soil matrix governs the amount of water storage in soil. It also controls the amount of runoff and erosion. Therefore, knowledge of water infiltration into soil is essential for determining strategies of soil and water conservation and minimizing the risk of nonpoint source pollution.

INFILTRATION

The rate of water infiltration into soil determines the following: 1) the time at which superficial water appears on the soil surface and 2) the amount of runoff that will form over the soil surface during rainfall or irrigation. The infiltration rate of a soil depends on soil texture, structure, moisture status prior to infiltration, continuity and stability of pores, and soil suction. Soil management including tillage influences these factors. Initially, water infiltrates into the soil at a rapid rate, but as time elapses, the infiltration rate attains a steady or asymptotic state, which approximates the saturated hydraulic conductivity of soil, K_s (Fig. 1). The high initial infiltration rate is observed when soil is dry. Under this situation, large suction-gradient exists (suction at the soil surface is zero or atmospheric pressure, and inside soil, it can be 2000–15,000 cm of H_2O depending on dryness of soil), which forces the water rather quickly into the soil.

INFILTRATION PROCESS

When rain falls or water is applied through sprinklers, the water supply rate may be either less than or greater than K_s of the surface soil. If the rate is less than K_s , all the water

falling on soil surface enters the soil. In this case, the infiltration rate is equal to the water supply rate; the rate of supply of water determines the infiltration rate, and the process of infiltration is known as “flux controlled.” On the other hand, if water is supplied at a rate higher than the maximum infiltration rate of soil, the soil–water transmission properties determine the amount and rate of actual infiltration. Infiltration rate in this situation is called “profile controlled.” When water infiltrates into a dry soil, the progress of water movement is observed by the darkened color of soil, as it gets wetter. There exists a sharp downward moving boundary between the wet region and the underlying dry region, which is known as the “wetting front.”

If the water supply rate is greater than K_s and the soil is dry, then for a while all the water enters the soil. In this case, the rate at which water enters the soil is greater than K_s . This occurs because water flows in response not only to gravity but also to soil suction. Sooner or later, the supply rate begins to exceed the capability of the soil to absorb the water. At this point, water begins to build up on the soil surface and runoff begins. Runoff can also occur if the soil becomes saturated above an impermeable layer, or if the soil has a layer in which K_s is less than that of the layers above it.

The time between the start of the rainfall and the initiation of runoff is known as the “time to ponding.” The infiltration rate continues to decrease asymptotically and approaches K_s . The steady-state infiltration rate (i_c) is also termed the “steady-state infiltrability.” It is approximately the same as the field saturated K_s of the surface soil. Basic infiltration rates for some soils are given in Table 1.

FACTORS AFFECTING THE INFILTRATION PROCESS

1. Soil properties: The i_c is approximately equal to K_s . Therefore, soils with higher K_s tend to have more

Fig. 1 A schematic representation of processes during a rainfall or irrigation event along with the components of hydrological cycle.

infiltration and less runoff. In addition, the pore-size distribution influences the rate of change of infiltrability. Generally speaking, the wider the range of pore sizes, the more gradual the change in the infiltration rate. The pore-size distribution is a mirror image of the particle-size distribution.

2. Initial moisture content: If the initial moisture content of soil is high, the initial infiltration rate of soil is low. For saturated soils, the infiltration rate approaches K_s almost instantaneously.
3. Rainfall: For rainfall or water supply rates less than K_s in a deep homogeneous soil, infiltration may continue indefinitely. For a given rainfall rate, the longer is the time to ponding, more gradual is the change in infiltration rate. Extremely high rainfall rates may cause slaking of aggregates at the soil surface leading to surface sealing or the formation of soil crusts.
4. Surface sealing and crusting: Change in K_s of the surface soil by slaking has a strong influence on the infiltration rate. The formation of a 5-mm-thick seal can lead up to a 75% decrease in infiltration rate of soil.
5. Layered soils: When the wetting front in the soil reaches a layer with either a coarser or a finer texture, there is a decrease in the infiltration rate for some time. If the layer has a coarser texture, the infiltration rate will recover when the large pores in that layer become saturated. For soil in which the layer is fine textured, the infiltration rate will stay low.

Table 1 Basic infiltration rates for various soil types.

Soil type	Steady-state infiltration rate (mm h ⁻¹)
Sand	<30
Sandy loam	20–30
Loam	10–20
Clay loam	5–10
Clay	1–5

Source: Adapted from Hillel.^[1]

6. Entrapped air: If air is trapped in the soil, K_s is reduced. Water infiltration into the soil is also restricted.

INFILTRATION MODELS

A range of conceptual and empirical models has been developed to predict water infiltration rate of soil as a function of time or the total quantity of water infiltrated into the soil. Common symbols used in these models are as follows: i for the infiltration rate, I for cumulative infiltration, t for time, and i_c for equilibrium rate of infiltration. When t is large, i_c approaches K_s .

Green–Ampt Infiltration Model

Green and Ampt^[2] made several simplifying physical assumptions to develop a mathematical relationship for predicting infiltration rate. The soil–water profile of infiltration was considered to be a step-like profile, and infiltration into the soil was assumed to be piston flow going progressively deeper with time. The soil profile was considered homogeneous and isotropic; therefore, K_s is unique:

$$i = K_s + bI^{-1} \Leftrightarrow i = i_c + bI^{-1} \quad (1)$$

where b is a constant. The Green and Ampt^[2] model uses an approximate description of actual flow regimes.

Kostiakov Equation

The Kostiakov^[3] equation for cumulative infiltration (I) and infiltration rate (i) can be expressed as follows:

$$I = Bt^{-n} \quad (2)$$

$$i = Bt^{-n-1} \quad (3)$$

where B and n are constants. These parameters do not have a physical meaning and can be obtained by fitting the equation to the experimental data. It can be inferred from Eq. 3 that at $t=0$, i approaches ∞ . However, as t increases, i tends to become zero. Therefore, the equation explains the horizontal infiltration, and the Kostiakov^[3] equation for vertical infiltration is inadequate.

Horton Equation

Horton^[4] equations for cumulative infiltration (I) and infiltration rate (i) are given as follows:

$$I = i_c t + \frac{i_0 - i_c}{\alpha} [1 - e^{-\alpha t}] \quad (4)$$

$$i = i_c + (i_0 - i_c)e^{-\alpha t} \quad (5)$$

where i_0 is the initial infiltration rate at $t=0$. The constant α determines the rate at which i_c approaches i_0 . Unlike other

Table 2 Comparison of various infiltration equations.

Parameter	Green–Ampt ^[2]	Kostiakov ^[3]	Horton ^[4]	Philip ^[5]	Holtan ^[6]
Theory	Physically based	Empirical	Empirical	Physically based	Empirical
Surface ponding	Required	Not required	Not required	Required	Not required
Initial infiltration	Infinite	Infinite	Finite	Infinite	Finite
At large time	Steady infiltration = K_s	Zero	Steady infiltration = K_s	Steady infiltration = K_s	Steady infiltration = K_s

Note: K_s , saturated hydraulic conductivity of soil.

equations, the Horton equation has a finite infiltration rate, i_0 at $t=0$. The equation is somewhat cumbersome as it has three constants that need to be evaluated experimentally. The decrease in infiltration rate with time is attributed to a number of factors, such as the closure of soil pores by a swelling soil, erosional deposit, and compaction due to raindrop impact.^[4]

Philip Equation

Philip^[5] provided a rigorous mathematical solution of flow equation applied to vertical infiltration into an infinite deep uniform soil in terms of a power series. In practice, first two terms of the power series are enough to describe steady infiltration through a soil profile as follows:

$$I(t) = St^{0.5} + At \quad (6)$$

$$i(t) = \frac{1}{2}St^{-0.5} + A \quad (7)$$

where S is the sorptivity. According to Philip,^[5] as t approaches infinity, the infiltration rate decreases to a finally asymptotic value, and the coefficient A can be replaced by K_s of upper layer.

Holtan Equation

The Holtan equation^[6] for infiltration rate in soil is again a two-form mathematical equation as follows:

$$i = i_c + af^n \quad (8)$$

where i_c is the equivalent infiltration rate and f is the available porosity as depleted by infiltration volumes, which can be expressed as follows:

$$f = M - I \quad (9)$$

where M is the water storage capacity of the soil above the first impeding stratum. It can also be expressed as total porosity—antecedent water content of soil, in depth units. I is the cumulative infiltration at that time.

$$i = i_c \quad \text{for } I > M \quad (10)$$

As long as $0 \leq I \leq M$, Eq. 9 is consistent; however, for $I > M$, the $(M - I)^n$ becomes positive or negative depending on the value of exponent n . Also, in the absence of an impeding layer, Holtan^[6] did not discuss the meaning of M . A comparison of all the infiltration equations discussed above is given in Table 2.

CONCLUSION

Infiltration is the vertical downward entry of water into the soil. It is an important component of the hydrological cycle, which recharges the soil and the groundwater resources underneath. The rate of infiltration of water into soil controls the amount of water storage, runoff, and erosion of the soil. Knowledge of water infiltration into soil is essential for determining strategies of soil and water conservation and minimizing the risk of nonpoint source pollution. Several mathematical relationships are available in literature, which can predict the rate and accumulative amount of water infiltration into soil.

Abstract

Water is a vital resource for food and fiber production. Irrigated farmlands in the semiarid to arid regions of the world contribute about 36% of the total production. As the human population increases, more irrigation water will be needed to meet the greater food demand. However, the supplies of usable and renewable freshwater are scarce. Agriculture is already facing a stiff competition for freshwater supplies from drinking, industrial, and recreational uses, even in the United States that has vast resources. The only answer is to conserve water through judicious management for all uses. In agriculture, the management of soil water based on scientific principles can help to increase water use efficiency, reduce losses, and prevent secondary salinization of groundwater resources, a common problem in irrigated areas of the world.

WATER FLOW

The theories of water flow in the integrated soil–plant–atmosphere system or continuum have vital field applications for soil water management under both rainfed and irrigated agriculture. During the last years, the increase in our basic understanding of soil water entry (infiltration), redistribution, retention, and uptake by plants has changed the old concepts of field capacity (water-holding capacity) of soils and the water available for plant growth ingrained in the traditional soil water management for plant production. The field capacity is no longer considered a constant intrinsic property of soil, but rather a continually decreasing soil water content, albeit at a slow rate of internal drainage.^[1,2] Factors such as the impeding or coarse-textured layers in the soil profile, pre-infiltration wetness, depth of the groundwater table, and surface evaporation rate influence the field capacity value.^[3–5] Similarly, the concept that soil water is equally available to plants in the range of soil water contents from field capacity to permanent wilting^[6] has been shown to be invalid^[7] and replaced by a dynamic concept of water availability to plants. It is postulated that the rate of water uptake that would sustain normal plant growth at any time depends not only on soil water status but also on the atmospheric conditions and properties of the plants.^[8–10] Atmospheric conditions dictate the evapotranspiration (ET) demand, or the rate at which the plant is required to transpire and absorb water from the soil to maintain its turgidity. Rooting depth, density, proliferation, extension, physiological adjustment of plant to water stress, and soil's unsaturated conductivities determine the soil water content at which the actual ET falls below the demand ET. These conditions also determine the

water content or soil water suction at which the plants will wilt. This new dynamic concept of soil water availability has tremendous implications for soil water management. This concept requires that irrigation applications be more flexible, based on meteorological conditions, plant growth stage, root system, and soil properties.

The knowledge of water flow in the soil–plant–atmospheric continuum needs to be combined with the knowledge of heat flow, nutrient processes, plant growth, and management effects in order to attain the best scientific management of soil water. However, the interactions among these components of the agricultural system are highly complex, dynamic, and difficult to comprehend. Fortunately, the modern technology has allowed us to develop computer models of the entire agricultural systems that incorporate these interactions.^[11–14] Therefore, computer models of this nature are useful as research and management guides for efficient use of water and nutrients under varying weather and climatic conditions. Modeling may be used for all areas of soil water management in a variety of ways—from designing an irrigation and drainage system for uniformity and effectiveness, to comparison of soil and water conservation practices, to simulation of the entire soil–plant–atmosphere continuum on a day-to-day basis for making decisions on water, fertilizer, or pesticide applications. Although there are many gaps in our knowledge at present, the models are developed well enough to use them as guides for optimum use of resources. This entry illustrates the applications of models in soil water management for plant production through examples. (Readers interested in the theories and assumptions underlying these models and the extent of their validation should see the cited references.)

Table 1 Management practices, timing, and application options in RZWQM.

Management practice	Timing options	Application options
Tillage operations	Plant growth cycle Specified date	29 Different implements User-specified intensity
Manure applications	Plant growth cycle Specified date	Surface broadcast Broadcast incorporated Injected fumigation Chemigation 15 Different types of manure available
Fertilizer applications	Plant growth cycle Specified date Preplant with topdress Preplant and topdress with plant demand trigger	Surface broadcast Broadcast incorporated Injected $\text{NH}_3\text{-N}$ Fertigation Nitrification inhibitor additives

Crop planting and harvesting	Multiple year same crop Multispecies rotations	Five Harvesting operations External crop models can be used
Irrigation applications	Fixed interval Specified dates Root zone depletion	Fixed amount Varying amounts Refill root zone

EXAMPLES OF APPLICATION

The U.S. Department of Agriculture-Agricultural Research Service Root Zone Water Quality Model (RZWQM) is an

agricultural system model with a Windows-based graphical user interface. It has been developed and used for a wide range of agricultural management problems, including both water quantity and quality.^[14,15] Table 1 shows the various

Table 2 Average yearly summary for manure and water management based on RZWQM.

Management option	Manure	Water applied (cm/event)	Silage yield ($\text{Mg ha}^{-1} \text{ yr}^{-1}$)	N uptake ($\text{kg N ha}^{-1} \text{ yr}^{-1}$)	N seepage ($\text{kg N ha}^{-1} \text{ yr}^{-1}$)	Denitrification ($\text{kg N ha}^{-1} \text{ yr}^{-1}$)	Volatilization ($\text{kg N ha}^{-1} \text{ yr}^{-1}$)
1	Full rate every year	20	25.2	254	196	130	11.1
2	Half rate every year	20	21.9	182	106	48	3.5
3	Full rate every 2 years	20	22.8	192	91	57	4.7
4	Full rate every 3 years	20	19.0	153	83	34	3.2
5	Full rate, split application	20	25.1	250	188	140	7.1
6	Full rate every year	10	25.8	307	116	141	11.1
7	Half rate every year	10	22.7	228	49	50	3.5
8	Full rate every 2 years	10	22.9	232	39	59	4.7
9	Full rate every 3 years	10	20.1	186	40	35	3.2
10	Full rate, split application	10	25.6	302	109	150	7.1

Note: Full manure application rate was 44.8 Mg ha^{-1} , and half rate was 22.4 Mg ha^{-1} . Manure was applied on October 15 for one application and October 15/April 1 for split application (22.4 Mg ha^{-1} each).

Source: From Ma, Shaffer, et al.^[16]

management practices simulated in RZWQM that affect soil water management for plants. This model can be used to address questions such as the amounts and timings of irrigation water, fertilizer, and pesticides applications under various tillage and cropping schemes in different soil types (Table 1). Table 2 shows the results of an example application of RZWQM for water and manure management in eastern Colorado from Ma et al.^[16] The field has been used for corn silage production for more than a decade with manure application every fall after harvesting. Irrigation water was applied 4 to 6 times during the months of July and August at a rate of 20 cm per event. Management Option 1 was the simulation result under management practices. As shown in Table 2, reducing water irrigation to 10 cm per event not only increased yield and nitrogen (N) uptake, but also decreased N losses.

Another example application of RZWQM is to answer questions on when and how much to irrigate. A common practice is to apply irrigation at a fixed time interval and a fixed amount of water for each irrigation. This practice disregards the water actually used by the crop in response to the atmospheric ET demand. A more scientific way is to link irrigation timing and amount to soil water contents in the root zone; e.g., the irrigation is triggered when the soil water storage falls below a certain lower limit of the so-called available water, arbitrarily defined as soil water content in equilibrium with 33 kPa (1/3 bar) water suction minus the soil water content at 1500 kPa suction. The irrigation is stopped when the soil water storage is filled to a certain upper limit of available water. What the lower and upper limits of available water for triggering and stopping irrigation should be depends on the soil type, crop, and climatic conditions in the area. A system model will be a good guide to determine optimal limits for an area. For the eastern Colorado site noted previously, on a Vona sandy loam soil, RZWQM-simulated average corn silage yields, N uptake, and N leaching at different irrigation amounts are shown in Fig. 1. The lower limit of available water to trigger irrigation was varied from 10% to 90%, and the upper limit to stop irrigation was varied from 50% to 90%. The irrigation period lasted up to 100 days after planting. These results indicate that the irrigations triggered when the soil water content falls to about 20% of the available water and stopped when the soil water storage is filled to about 50% of available water gave the best results—maximum N uptake and silage yield and minimum nitrate-N leached.

A third example is the use of the GOSSYM model for cotton crop management from Lemmon.^[12] GOSSYM was developed by a team of scientists in Mississippi and South Carolina, in the United States.^[17] It simulates the growth and development of cotton on an organ-by-organ basis (roots, stems, leaves, blooms, squares, and bolls), as well as the transport and uptake of water and nutrients through the soil profile. The model is driven by daily weather variables, such as solar radiation, rainfall, and

Fig. 1 The responses of yearly average N uptake (A), silage yield (B), and nitrate-N leached (C) to irrigation according to degree of root zone water depletion, as simulated by RZWQM. **Source:** From Ma, Shaffer, et al.^[16]

maximum–minimum air temperatures, and requires input data on soil properties and soil fertility. GOSSYM is used to determine irrigation schedules, N requirements, and crop maturity dates. An example of how GOSSYM simulation results are used is shown in Fig. 2.^[12] The N and water stress values are ratios of the amount of N or water used to the amount needed for full growth at different times. The first row of graphs was produced after the third N application. These results show N and water stresses

Fig. 2 Graphs produced by Commax from the results of GOSYM simulations, showing the process whereby Commax reduces the water stress and then the N stress.

Source: From Lemmon.^[12]

and their projected effects on yield organs and cotton. The second row of graphs is the simulation results of increasing irrigation schedule to reduce water stress. However, increased irrigation results in increased N stress. The third row shows the simulation result of adding a small N application (fourth N application), which reduces N stress and increases yield. In the fourth row, N application was increased for the fourth N application, which eliminated N stress. However, this increased application also resulted in some new vegetative growth and squares near the harvest time. Thus, the fifth row presents optimal results with a moderate N application rate. These simulation results have convinced Mississippi cotton growers to apply

additional N that was not planned originally and resulted in increased yield.

THE FUTURE

The results presented show the value of the models to guide soil water management for plant production in complex agricultural systems. At the dawn of the 21st century, computers are playing a central role in managing industries, businesses, and many other aspects of life. Their use in managing water and other natural resources and environmental quality is increasing. It is time that computer models

of agricultural systems be integrated with all field research, so that the models continually capture new knowledge as it becomes available. The models should then be used to guide agricultural management under varying climatic and weather conditions.

Water Management: Harvesting

Gary W. Frasier

U.S. Department of Agriculture (USDA), Fort Collins, Colorado, U.S.A.

Abstract

Collecting precipitation for reuse is commonly called water harvesting. Water harvesting is an ancient practice. This entry presents the uses for harvested water, types of systems, and cropping considerations for water harvesting.

INTRODUCTION

Without water, land has no value and man cannot live. Yet with few exceptions, in most places on earth, there is sufficient water available on an annual basis for man not only to survive but also to live. This water comes in the form of precipitation, and all that is required is a means of collecting and storing this precipitation from the sky. Accessing this type of water supply—collecting precipitation for reuse—is commonly called *water harvesting*. In more technical terms, water harvesting can be defined as “the process of collecting and storing precipitation (rain or snow) for beneficial use from an area that has been treated or modified to increase precipitation runoff.”^[1]

Water harvesting is an ancient practice dating back at least 9000 years when it was used in the Edom Mountains of Southern Jordan.^[2] It is probable that the first water harvesting system was nothing more than a simple depression that filled with water runoff from an uphill area. Evidence of extensive water harvesting systems used 3000–4000 years ago have been found in various areas of the Middle East. Many of these ancient systems were located in areas where the annual precipitation was less than 200 mm per year.^[3] Often in arid climates, small rain-filled depressions can be found at the bottom of rock outcroppings which provide drinking water for wildlife.^[4] Rain-filled depressions are being used for domestic drinking water supplies (Fig. 1). Water harvesting techniques are used in areas such as Israel, Egypt, Jordan, Mexico, Australia, and throughout the parts of the United States.

GENERAL DESCRIPTION

Water harvesting systems are frequently grouped into two categories, depending on the intended use of the collected water. Collected water can be used for domestic purposes (e.g., drinking by humans and animals) or crop growing. All water harvesting systems, whether used for drinking water supplies or crop growing, have two major components as

follows: a precipitation collection area (i.e., catchment or runoff area) and a water storage facility. Surfaces of the catchment areas range from rock outcroppings or smoothed–compacted soil to chemically treated or membrane-covered soil, and building rooftops. The storage facility can be a pond, cistern, tank or, in the instance of crop growing, the soil profile.^[5]

RUNOFF FARMING

Runoff farming is a form of water harvesting used specifically for growing crops. Essentially, runoff farming maximizes the effect of limited precipitation over a large area by collecting the surface runoff and applying it to a smaller area. In its simplest form, a portion of land is dedicated to precipitation collection, and the collected water is diverted onto a crop-growing area where it is allowed to infiltrate into the soil for use by plants. The crop area is usually smaller than the water collection area. The collected water can be applied directly to the crop area from the catchment area during the precipitation event or stored for later application using an irrigation system. Runoff farming is not necessarily a technique for increasing crop production but rather a method for sustaining crop production or reducing the risk of crop failure caused by drought.

Types of Systems

Runoff farming systems can be grouped into three general types, depending on the physical arrangement of the catchment area and the crop-growing area (Table 1). The first method, called *floodwater farming*, diverts runoff flowing down a channel during a storm event directly onto a crop area (Fig. 2).

The second method is called *micro-catchment farming*. With this method, each plant or group of plants is assigned a small runoff area situated directly upslope of the growing area. The runoff water is held in the growing area by small earthen berms until it has infiltrated into the soil. This

Fig. 1 A water harvesting system used for drinking water supplies on First Mesa of the Hopi Indian Reservation in Northern Arizona. The catchment surface is a natural rock outcropping, and the collected water is stored in an excavated cistern at the lower end.

technique has been used extensively for tree crops such as pistachio, olive, and almond.

The third method of runoff farming involves a combination of both on-site runoff water and irrigation with excess runoff water from a stored source. The land is formed into a series of large ridges and furrows, and crops, such as fruit trees or grapes, are planted in the furrow bottom. Water runs from the side slopes of the ridges into the crop area. Excess runoff water not directly infiltrated into the planted area continues down the center of the furrow into a storage facility. At a later date, the water is pumped back onto the crop area as needed, using an irrigation system.^[3]

Site Characteristics

The soil in the area of a runoff farming system must serve two diametrically opposed purposes. On the runoff collecting area, the soil must have a low rate of water infiltration and be resistant to soil erosion by water. The soil in the cropping area should have a high infiltration rate with a high water-holding capacity. Many Loess soils are ideally suited for runoff farming applications because they have a high water-holding capacity yet form surface crusts that promote precipitation runoff.^[6]

The relative sizes of the catchment area to the cropping (run-on) area depend on the size and intensities of the

Fig. 2 Floodwater farming near Matrouh, Egypt.

precipitation events, the infiltration rate on the catchment area, and the quantity of water required. Large storms (>25 mm) of moderate to high intensity can provide significant quantities of water from relatively small areas. Conversely, low-intensity storms on soils with high infiltration rates will require larger runoff areas to provide the same quantity of runoff. Typically, the runoff area is 5 to 20 times larger than the cropping area.

Catchment area slopes should be steep enough to maximize runoff and minimize surface storage in depressions, yet flat enough to prevent soil erosion.^[7] To minimize potential soil erosion on the runoff collecting area, overland flow distances should be minimized and the flow maintained as shallow sheet flow. Concentrated water flows should only be used in areas where channels are protected from erosion and designed to carry the flow.^[8] Landform areas with undulating, gently sloping land are best suited for runoff farming. The steeper portions of the land provide the water collection function, while the flatter areas are used for growing crops. In some instances, the crop area is shaped into a series of small terraces with essentially no slope in the planted area. This allows for a better distribution of the collected water in the soil profile.

Successful runoff farming systems include both adequate water management and cropping practices suited to the local area. Good water management includes reducing seepage and evaporative losses of the collected water. For maximum long-term effectiveness, water harvesting systems must have scheduled timely maintenance and repair. Many systems have been adequately designed and constructed, yet have failed to supply the anticipated quantities of water within a relatively short time interval because of little or no maintenance. Usually, maintenance or repair can be accomplished in a short period of time without great expense.

CROPPING CONSIDERATIONS

Cropping practices must include plants that are capable of efficiently using available water yet withstanding

Table 1 Types of runoff farming systems.

Type	Technology level	Crops	Organization
Floodwater farming	Moderate to high	Annual grains and trees	Community
Micro-catchments	Low to moderate	Trees and shrubs	Family
Combination	High	Trees and vines	Community

prolonged time intervals of limited or non-existent water. Good cropping practices also must recognize that water requirements for plant establishment frequently differ from water requirements for mature plants. During the plant establishment phase, rooting systems are usually shallow, which necessitates that water be available in the upper layers of the soil profile. Under these conditions, there is also the potential for significant loss of soil water by evaporation from the unprotected (non-shaded) soil surface. Meeting these water requirements usually means applying water at a frequent interval during the plant establishment phase. Once the plant has achieved some aboveground biomass which shades the soil surface, the direct loss of water from the soil surface is lessened. Also, the deeper rooting system of mature plants allows a larger volume of soil to be used to retain the collected water until it is needed.

A feature that is not controlled but is important to the success of runoff farming systems is the precipitation characteristics of the area. The maximum net effectiveness of the water harvesting system is achieved if the precipitation occurs during cooler weather when evapotranspiration rates are the lowest. Precipitation intensities must be greater than the infiltration rate of the catchment area. The timing of the precipitation compared with the water needs of the crops must be considered. Less extensive systems—especially water storage—are required if precipitation occurs during the cropping season. This reduces the length of time necessary to store the collected water. Selecting crops that are suited for or immediately following the normal rainy periods will improve the chances for a successful runoff farming system.

Water Management: Use Efficiency

David C. Nielsen

U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS),
Akron, Colorado, U.S.A.

Abstract

In semiarid regions where lack of water is limiting crop yield, water use efficiency needs to be maximized to get the most from this scarce resource. This can be accomplished through several management techniques to improve the cropping environment that includes reducing tillage to maintain surface crop residues, minimize evaporation, and trap snow; applying irrigations only during critical growth stages; matching fertilizer application rates to the expected available water condition; and employing crop rotations that reduce or eliminate fallow periods.

INTRODUCTION

In semiarid regions of the world, water is generally the most limiting factor to crop production. Therefore, a primary objective of cropping systems in these regions is to improve water use efficiency, i.e., get the most production of marketable yield for each unit of water used by the cropping system. There are many definitions of water use efficiency,^[1,2] but this discussion uses the following: water use efficiency is the ratio of crop grain yield to the evapotranspiration used to produce that yield. The following discussion will deal mostly with enhancements to water use efficiency that are a result of altering and improving the cropping environment in semiarid regions.

An extremely important method for enhancing water use efficiency is to get more water to be used for plant transpiration and less for evaporation. This can take two forms in a dryland cropping system: increasing precipitation storage efficiency and growing a crop in place of a fallow period.

REDUCING TILLAGE/MAINTAINING CROP RESIDUES

Increasing precipitation storage efficiency through soil-surface water evaporation reduction during the non-crop period of a crop rotation can be accomplished by 1) reducing tillage to minimize the number of times moist soil is brought to the surface and 2) maintaining residues to shade the soil surface, reduce convective exchange of water vapor at the soil-atmosphere interface, reduce runoff by preventing surface crusting, and catch snow.

Precipitation storage efficiency increases as tillage is reduced during the summer fallow period (Fig. 1A).^[3,4] The increased soil water storage is a result of both maintaining crop residues on the soil surface and reducing the number of times that moist soil is brought to the surface.

Data from western Kansas showed water use efficiency increasing by 28% for corn, 17% for sunflower, 10% for soybean, and 7% for grain sorghum. This efficiency was found when a no-till production system was used in place of a conventional tillage system,^[5] using three- or four-sweep plow tillage operations to control weeds in the fallow period prior to crop establishment.

The effect of residue amount on precipitation storage efficiency using data from the three Great Plains sites is shown in Fig. 1B.^[7] Increased precipitation storage efficiency during the 14-month fallow period of a winter wheat-fallow system resulted from increasing amount of surface wheat residue. Crop residues reduce soil water evaporation by shading the soil surface and reducing convective exchange of water vapor at the soil-atmosphere interface.^[8,9] Additionally, reducing tillage and maintaining surface residues reduce precipitation runoff and increase infiltration, thereby increasing precipitation storage efficiency.^[10]

The reduction in convective exchange of water vapor is more effective in standing crop residues (compared to flat residues) because wind speed is reduced near the soil surface by the standing residue.^[11–14] Reductions of up to 50% in potential surface soil water evaporation have been demonstrated when wheat stubble height after harvest was increased from 0.1 to 0.5 m, or when stem populations of short (0.1 m) standing wheat stems were increased from 100 to 600 stems m⁻².^[15]

Standing crop residues also increase the soil water available for crop production in the central and northern Great Plains by increasing snow deposition during the overwinter period.^[6,16–19] Reduction in wind speed within the standing crop residue allows snow to drop out of the moving air stream. The greater the silhouette area index (SAI = height × diameter × number of stalks per unit ground area) through which the wind must pass, the greater the snow deposition. Typical populations and heights of standing sunflower stalks after harvest (SAI = 0.03–0.05 m² m⁻²)

Fig. 1 Precipitation storage efficiency as influenced by (A) tillage method during the 14-month fallow period in a winter wheat–fallow production system and (B) crop residue level on the soil surface.

Source: Data from Smika & Wicks,^[3] Tanaka & Aase,^[4] and Caprio.^[6]

can result in an overwinter soil water increase of about 10–12 cm when winter precipitation is near normal in amount and number of blizzards in northeast Colorado^[20] (Fig. 2). Overwinter soil water storage in North Dakota increased 0.24 cm for each centimeter increase in wheat stubble height because of greater snow trapping.^[21] Because of the drifting and packing of snow that occurs in standing crop residues, precipitation storage efficiencies can be very high. Overwinter precipitation storage efficiencies in excess of 100% in standing sunflower stalks have been reported in some years^[20] as stalks collect snow blown in from adjacent areas without standing residues. Average overwinter precipitation storage efficiency of 55% has been reported for wheat stubble in northeast Colorado.^[22]

The increased precipitation storage efficiency from maintaining residues on the soil surface will result in greater amounts of stored soil water. These higher soil

Fig. 2 Influence of sunflower SAI on overwinter soil water change at Akron, Colorado.

Source: From Nielsen.^[20]

water contents at planting have been shown to lead to higher crop yields for winter wheat and proso millet.^[23] The water use efficiency also increases with increased available soil water at planting, but only in years with normal or below normal growing season precipitation. In above-average precipitation years, when growing season precipitation makes up a higher percentage of total water use, there is no increase in water use efficiency with increasing water content at planting.

SHIFTING WATER USE TO CRITICAL GROWTH STAGES

Another method for enhancing water use efficiency is to shift growing season water use so that a greater proportion of the total is occurring during the more critical growth stages of flowering and grain filling and less in the not-so-sensitive vegetative growth stage. When a growth retardant was applied to restrict vegetative development and leaf area in corn, water use during the vegetative stage was reduced, increasing the amount of water available for use during reproductive stages, resulting in a 16% increase in water use efficiency.^[24] Dryland winter wheat water use efficiency in the southern High Plains ranged widely from 0 to 36 kg ha⁻¹ cm⁻¹ due to the wide range in amount and seasonal distribution of precipitation.^[25] Winter wheat water use efficiency at Akron, Colorado, increased linearly as the amount of precipitation falling between 15 May and 25 June (jointing through grain filling) became a higher percentage of the total growing season precipitation.

Similar results are reported for experiments with limited irrigation in which water is withheld during vegetative growth and applied during flowering and grain filling. When a set amount of limited irrigation was applied to

corn, sorghum, and wheat during flowering and grain filling, as opposed to applications throughout the entire growing season, water use efficiency increased by 19%, 42%, and 29%, respectively.^[26] Similarly, water applied to winter wheat during the boot to anthesis stages averaged twice the yield response of water applied during tillering through jointing, without substantially increasing seasonal evapotranspiration.^[25]

APPROPRIATE FERTILIZER APPLICATION

In most cases when water supply is fixed, any management factor that increases yield will increase water use efficiency because evapotranspiration is little affected by the management.^[2,27] For example, dryland winter wheat in northeast Colorado had increased water use efficiency with increased level of applied nitrogen (N) fertilizer (Fig. 3).^[28] However, water use efficiency can decline when high levels of N fertilization produce excessive vegetative growth that uses up the limited soil water supply early in the growing season.^[29] When water availability is low, plants grown under extremely high N fertility conditions may undergo more water stress during the more critical flowering and grain-filling stages than plants grown under lower fertility. Consequently, grain yield was reduced at the two highest fertilizer application rates while water use remained nearly the same for the highest N application levels.

REDUCING OR ELIMINATING FALLOW

One of the most productive ways of improving cropping system water use efficiency is to eliminate fallow periods. Cropping systems in the Great Plains have traditionally relied on the practice of summer fallowing in which one

Fig. 3 Influence of N fertilizer application rate on winter wheat water use efficiency at Akron, Colorado.

Source: From Nielsen & Halvorson.^[28]

crop of winter wheat is grown every other year. The purpose of this was primarily to reduce the erratic yields (and sometimes total crop failure) associated with annual cropping. However, this practice is extremely inefficient in its storage and use of precipitation.^[30] Most of the precipitation received during the summer of fallow just preceding wheat planting in the wheat–fallow system is lost to evaporation. Intensifying cropping systems by reducing or eliminating fallow periods increases water use efficiency of the system.

Data averaged over 6 years at Akron, Colorado, show an 18% increase in water use efficiency through reduction of tillage in the wheat–fallow system, going from conventional tillage (35.5 kg ha⁻¹ cm⁻¹) to no tillage (41.9 kg ha⁻¹ cm⁻¹). When corn is added to the system such that two crops are produced in 3 years (wheat–corn–fallow), the water use efficiency increased by 55% (to 54.9 kg ha⁻¹ cm⁻¹). With the continuous wheat–corn–millet system, the water use efficiency increased by 82% (to 64.4 kg ha⁻¹ cm⁻¹). An even higher system water use efficiency (87.3 kg ha⁻¹ cm⁻¹) was reported in a continuous dryland cropping experiment (8 years) with barley, corn, and winter wheat, also at Akron, Colorado.^[31]

CONCLUSION

In semiarid regions where lack of water is limiting to crop yield, water use efficiency needs to be maximized to get the most from this scarce resource. This can be accomplished through several management techniques to improve the cropping environment that includes reducing tillage to maintain surface crop residues, minimize evaporation, and trap snow; applying irrigations only during critical growth stages; matching fertilizer application rates to the expected available water condition; and employing crop rotations that reduce or eliminate fallow periods.

Water Measurement: Methods

Des McGarry

Natural Resource Sciences, Queensland Department of Natural Resources and Mines, Indooroopilly, Queensland, Australia

Abstract

This entry compares four water measurement methods—thermogravimetric, neutron thermalization, frequency domain reflectometry, and time domain reflectometry.

INTRODUCTION

The measurement of soil water is fundamental to many agricultural, forestry, engineering, landscape dynamics, meteorological, and hydrological investigations,^[1] aimed at understanding soils' chemical, physical, mechanical, and biological functions and relationships.^[2] Measurements may be direct or indirect, field or laboratory based, occasional or continuous and include the size and time course of the soil moisture content and water movement into, through, retained by and passing out of a soil profile or specific soil layer. Several measurement techniques have been devised in response to these needs, and this entry will review aspects of four—thermogravimetric, neutron thermalization, capacitance [frequency domain reflectometry (FDR)], and time domain reflectometry (TDR). Less common techniques of measuring soil water, including ground penetrating radar, active and passive microwave, electromagnetic induction, and heat dissipation, whether *in situ* or by remote sensing, are reviewed elsewhere.^[3,4]

Here, emphasis will be on a comparison of the strengths and weaknesses of the four measurement techniques (Table 1). This draws on several, detailed reviews of soil water content and its measurement.^[1–4,9–15] Comparisons of the three indirect methods have been conducted.^[16–18] A detailed review of neutron, capacitance, and TDR probes and their use in measuring and monitoring soil water status are available,^[19] revised with a new set of case studies.^[7]

To provide a basis for comparison of the measurement techniques reviewed here, only a specific form of each apparatus will be discussed, namely apparatus that is used to measure soil water content profiles, i.e., water content at discrete, user-chosen depth intervals, commonly to 1 or 2 m depth. This is particularly important for the capacitance and TDR devices where there are many different designs. For the thermogravimetric technique, the determination of soil water profiles is conducted using either one continuous or many samples of individual, selected depths, obtained using thin-walled metal cylinders. Continuous cores are precisely cut into designated lengths to facilitate bulk

density calculation, and hence volumetric water content. For the three indirect measures, to obtain a similar profile of soil water contents as the thermogravimetric technique, the form of each apparatus discussed will be: for the neutron moisture meter (NMM), a “profiling meter”;^[6] for the capacitance probe, one or more pairs of cylindrical rings separated by a non-conducting plastic ring;^[20] and for the TDR, a “segmented probe” consisting of two parallel metal bars with resin between them, which utilizes diode shorting to achieve horizontal probe segmentation.^[21]

SOIL WATER CONTENT

Soil consists of a three-phase system composed of solid (soil particles), liquid (water and solutes), and gas (air), where the solid is not a continuous mass but is broken into individual grains or aggregates with spaces (soil pores) between them that can be filled with the other two phases (water and air). The per mass or per volume fraction of water in the soil is expressed as “water content” or alternatively “soil wetness.”^[2]

DIRECT AND INDIRECT MEASUREMENT OF SOIL WATER CONTENT

Direct techniques of determining soil water content are those where the water in a sample of soil is removed or separated from the soil matrix by evaporation, leaching, or chemical reaction^[15] with subsequent direct measurement of the amount of water removed. The first will only be considered here, where the water in a sample is removed by oven drying and the amount removed is determined by measurement of the change in mass of the sample.

Indirect techniques involve measurement of some physical or chemical property of the soil that is affected by or is a function of soil water content.^[1,4] The most common use of indirect techniques is to measure either the distribution of soil water content at one time or the

Table 1 Strengths and weaknesses of four methods of soil water measurement.

Thermogravimetric	Neutron	Capacitance	TDR
Strengths			
The standard, for characterizing soil water content An absolute, directly measured quantity Calibration standard for indirect methods Simple field and laboratory methods	Not destructive (after initial installation of access tube or probe) No need for laboratory drying, weighing, etc., after initial calibration		
	Can be calibrated to great precision	Robust and stable instrumentation	
	Operate to far greater depths than other methods, e.g., 96 m ^[5]	Fast response times—rapid data gathering (Fig. 1)	
	Zone of influence is largest of all indirect methods; radius range: 15–50 cm ub wet and dry soils, respectively ^[6]	Accuracy with site-specific calibration and good probe-soil contact No health and safety problems	
	Least affected by soil disturbance, smearing, and cracks (air gaps) near access tube	Automatic and continuous logging of water data over long periods (Fig. 1) Remote (telemetry) collection of data possible	
Weakness			
Destructive sampling required Large labor requirements Time consuming: transport, weighing, and drying of samples Provides neither immediate nor continuous water content Accurate bulk density measurement needed to convert to θ_v	Accuracy and precision of indirect methods depend on the uniquenesses of the relationship between the measured property and θ_v , and the minimal influence of other soil properties that are not soil water ^[4] Cost ^[7] Perceived health issues Statutory safety requirements: For all users To acquire, possess, use, relocate, travel with, and supply devices Licensing requirements	Small zone of influence of the electrodes Air gaps beside access tube give dielectric confusion; poor data Care required in access tube installation to achieve a tight fit with no air gaps Temperature sensitivity of some capacitance devices	Single calibration equation suitable for a wide range of soils Less sensitive to the several interferences commonly present in soils that effect capacitance

(Continued)

Table 1 Strengths and weaknesses of four methods of soil water measurement. (Continued)

Thermogravimetric	Neutron	Capacitance	TDR
Soil shrink—swell effects: Bulk density changes so θ_v requires determination over wide water content range Cracks cause problems with representative sample locations (Fig. 2) Necessary to present water data against a mass (not depth) coordinate ^[8]	Probes cannot be left unattended, so: Remote data collection impossible Inter-site travel laborious Repeated lifting of heavy equipment Lengthy stays at sites to manually work probe Wet weather access problems—leads to data gaps (Fig. 3) Repeated visits to probe location gives site tramping that may effect results Calibration required, though usually linear ^[6] Data not continuous (Fig. 3) and data collection cannot be automated Shrinkage cracks can effect values ^[9] Cannot perform measurements at several depths concurrently	Shrinkage crack influences may preclude use in moist to dry Vertisols Calibration required for accurate water content measurement, though factor calibration useable to assess relative differences in water content ^[7] Measure sensitive to <i>in situ</i> soil electrical conductivity—as salinity increases soil appears wetter that it is	Care in probe installation to achieve a tight fit Shrinkage crack influences may preclude use in moist to dry Vertisols Calibration necessary in “extreme” soil conditions, e.g., large clay content, ferritic soils (Oxusols), large organic matter levels

Source: From Gardner, Bell, et al.,^[1] Hillel,^[2] White & Zegelin,^[3] Topp & Ferre,^[4] Pikul,^[10] Evett,^[11] Starr & Paltineanu,^[12] Evett,^[13] Gardner,^[14] Gardner,^[15] Evett, Ruthardt, et al.,^[16] and Evett, Laurent, et al.^[17]

Fig. 1 Capacitance probe data collected at five depths (20, 30, 40, 60, and 80 cm) over a one-month period in an actively growing, irrigated cotton crop on a Vertisol, near St. George, Australia. The data for each depth are an arithmetically smoothed average of readings every 15 minutes (96 readings a day), collected remotely using telemetry to a telephone landline and then computer downloaded. The irrigation events are given (A, B, and C). Evident is 1) water infiltration to each depth at each irrigation, 2) even drying of soil water at all depths—suggesting actively extracting roots at all depths, and 3) diurnal fluctuations (a “night–day–night” example circled) in water extraction showing active and less-active plant growth (hence water extraction) during the day and at night.

Note: The lack of a site-specific calibration causes inability to present actual values of volumetric water contents for the y-axis. The y-axis is presented as a volumetric soil moisture percentage and is a repeatable number. The data are sufficient to plan the time and quantity of irrigation at the farm level.

change in soil profile water content over time at one or several places in a field or plot.^[1]

Thermogravimetric Technique

Gravimetric sampling combined with oven drying is generally accepted as both the standard, direct technique for characterizing soil water content as well as the calibration standard for many indirect soil water measurement techniques. Sampling, laboratory procedures, and calculations are described elsewhere in this encyclopedia and related volumes.^[10] In simple terms, field (or laboratory) wet soil samples are oven dried (commonly 105°C) to a constant mass and the gravimetric water content (θ_g) of the initial sample is expressed as the mass of water (g) per unit mass (g) of oven-dried soil.

Volumetric water content (θ_v) expresses soil water content in terms of the volume of water per unit volume of soil. The only direct method of determining volumetric water content is to obtain undisturbed soil samples, the volume of which is known. This is done most acceptably using

thin-walled metal cylinders of known volume.^[22] θ_v is calculated by multiplying θ_g with the dry soil bulk density^[10] and is the preferred expression of soil water content when considering water contents of different soils, water use under crops, and application rates in irrigation situations,^[19] as θ_v may be expressed as the equivalent depth of water because θ_v is numerically equal to the ratio of the depth of stored water per unit depth of soil. This greatly facilitates computations of soil water budgets where inputs of water (commonly in millimeters of water) from rain or irrigation are compared with outputs due to evapotranspiration and drainage.

The thermogravimetric technique has several important strengths as well as weaknesses (Table 1). Positives include the universally accepted methodology, utilizing commonly available laboratory equipment (balances and ovens), as well as the ability to measure unique, small depth (or spatial) increments (down to millimeter scale) if required. Negatives include the need for destructive soil sampling (particularly if replication done), transportation of samples (often of

considerable weight and bulk) to the laboratory, weighing, oven drying (to constant mass), and subsequent data calculations. The outcome tends to be small, time-specific (non-continuous) data sets that require significant physical effort and time to obtain (Fig. 4). Similar to all methods of determining soil water content, Vertisols (cracking clays) pose specific sampling challenges, particularly obtaining representative bulk volumes in dry soils (Fig. 2).

Neutron Thermalization

This indirect technique of determining soil water employs the NMM. The NMM was first used in the 1950s and

Fig. 2 An example of the challenges of obtaining a representative sample of soil water content in swell/shrink soils, exemplified on the soil surface of a Vertisol in an irrigated (but dry) wheat field, near Narrabri, New South Wales, Australia. The circles (each 100-mm diameter) represent four possible locations of a 100-mm diameter sampling ring. The “correct” soil water content would require sampling of, at best, a composite of all four. In addition, the selection of sampling location based on visible surface cracks may inaccurately sample lower depths as surface cracks do not necessarily continue vertically to depth.

became popular in the 1980s, when it was used extensively by consultants for irrigation scheduling.^[19] Principles, field procedures, calibration, and the associated derivation of data are described in detail elsewhere in this encyclopedia, in related volumes,^[11] and in several reviews.^[6,19,23–25] In simple terms, the neutron moderation technique is based on the response of fast moving neutrons that are slowed (thermalized) by an elastic collision with existing hydrogen particles in the soil. Hydrogen is present in the soil as a constituent of soil organic matter, clay minerals, and water. However, water is the form of hydrogen that is most likely to change from measurement to measurement.^[7] The volume fraction of water in the soil is obtained from a calibration equation that relates volumetric water content (measured by destructive soil core sampling) with the count ratio where the count ratio is the ratio of slow neutrons detected to the number of fast neutrons emitted when the probe is placed in a reproducible standard medium, commonly pure water.^[6] As with all the indirect methods presented here, consideration needs to be given to the “zone of influence” of the device, defined as that area in which a change in the moisture content of the soil will result in a detectable change in the detection systems of the different devices. Common to all devices, the zone of influence both surrounds and extends along some length of the probe and varies inversely with water content. Changes in the water content of the soil immediately adjacent to the probe have a far greater effect on the instrument readings than equivalent changes in water content occurring further away. The zone of influence for a NMM is approximately a sphere with radii of 15 and 50 cm in wet and dry soil, respectively.^[6]

In terms of calibration, and common to all of the indirect measurements, if absolute volumetric water content data are required (compared with changes in soil water content), then specific site calibration is required (rather than the “universal” or soil type specific calibrations supplied by some manufacturers). Site-customized calibration removes the potential effects that several sources of interference may have on the concentration of thermalized neutrons, including bulk density, alternate sources of hydrogen ions in the soil (e.g., organic matter and certain clay minerals), soils high in iron, magnetite, and chloride salts.^[6] Strengths and weaknesses of the technique are detailed in Table 1. Positives include linear calibration of count ratio and volumetric water contents over a wide range of water contents, the device is considered as the most accurate (indirect) method of determining soil water content (with site-specific calibration),^[6] and the large zone of influence (considered by some disadvantage as it averages spatial variation in water content) causes less effect of air gaps around access tubes. Negatives include cost (relative to capacitance probes), licensing and transport restrictions, inability to automate what can be lengthy data collection times, and the need for repeated site access, which can alter the hydrological representativeness of the monitored location.

Fig. 3 Time series data collected at four depths over a one-month period by a commercial cotton crop consultant using a NMM in an irrigated cotton field, St George, Queensland, Australia. The three irrigation events are given as A, B, and C. Evident is the inability of the consultant to sample frequently enough to monitor the soil response(s) to the irrigations, despite an attempt to sample on a five-day interval. Excess workload caused a missed reading event on January 28, 2000.

FDR (Capacitance) and TDR

The second and third indirect techniques of determining soil water—FDR and TDR—are both based on measuring the dielectric constant of the soil water media.^[4] The dielectric constant is a measure of the capacity of a non-conducting material to transmit electromagnetic waves or pulses.^[7,19] The dielectric constant of water is relatively large, whereas the values for both soil solids and air are far smaller. The value of the dielectric constant is largely determined by the fraction of water present—as the water content of the soil increases, the dielectric constant increases.^[2] Studies of capacitance and soil dielectric properties to measure soil water content date from the 1930s, but advances in reliability and affordability of electronics and microcomputers have greatly increased this usage.^[3]

Frequency Domain Reflectometry

FDR measures the soil dielectric by placing the soil (in effect) between two electrical plates to form a capacitor.^[7]

When an alternating voltage is applied to the electrodes, a frequency can be measured. This frequency varies with the soil dielectric constant. Using calibration protocols, the

functional relationship between oscillation frequency and water content can be determined.^[7,12] Capacitance probes are the subject of several reviews of their theory, field procedures, and calibration elsewhere in this encyclopedia, in related volumes,^[12] and in several reviews.^[1,3,4,16–20] There are several probe designs^[7] although only one will be considered here, where one or more pairs of cylindrical metal rings separated by a non-conductive plastic ring are mounted on a plastic rod.^[20] This probe is designed for semipermanent (commonly season-long) insertion into a previously installed plastic access tube^[12] with the multiple sensors located at set depths to monitor soil water up to 2 m depth. The zone of influence for this configuration is primarily within 10 cm radius of the access tube and about 10 cm along the rod, centered at the insulator between the two metal rings.^[20] However, 90% of the influence is within a zone that stretches from about 3 cm above and below the center of the plastic ring and 3 cm in the radial direction.^[26] Strengths and weaknesses of the technique are detailed in Table 1. Positives include low-cost, highly sensitive, robust, and stable instrumentation, fast response time, ability to measure time steps seconds apart, ease of use, loggable and amenability to automated and telemetry operated real-time monitoring.^[4] Negatives include smaller sphere of influence (than NMM),

Fig. 4 An example of soil water data from the thermogravimetric method. In this example, curved lines (with standard error as dashed lines) have been fitted to the original data. The data are from a field trial on a Vertisol, so are presented on a mass coordinate basis. Soil cores were collected in triplicate in 0.1 m increments to 1.5 m after each of two crop irrigations: on each of (A) 10, 25, and 40 days after one and on (B) 5 and 78 days after another. The total number of soil samples was 245; individually weighed, before and after oven drying, and the data manually entered for water content calculation; a very large workload for minimal output.

Source: From McGarry & Malafant.^[8]

hence measurement reliability influenced by air gaps around access tubes, and difficulties with soil sampling (for volumetric water content) within the device-measured volume. Temperature effects are under discussion.^[4]

Time Domain Reflectometry

There have been many reviews of TDR theory, the underlying physics, the various apparatus available, their field and laboratory usage, and the advantages and disadvantages of the technique.^[13,7,16–19,21,27] TDR measures the time taken for an electromagnetic pulse (a fast rise voltage step) to travel along metal rods placed in the soil, with the travel time being a function of the apparent dielectric constant of the soil.^[28] Because the travel time of the signal depends on the dielectric constant of the soil, it is possible to obtain a linear calibrated relationship between the travel time and the soil water content.

A variety of forms of TDR soil probes with different application capabilities are available.^[7,21] Parallel rods

were the most common form and facilitated water content measurement at selected depths. The rods were either pushed into the soil surface or inserted at selected depths in the soil profile, commonly into the sides of an access trench. Further, segmented probes have been devised to facilitate concurrent measurement of water content at up to five soil depths, so providing the water content profile and the total stored water profile from a single installation.^[21] This type of soil moisture probe is designed to emulate a two-wire, parallel conductor transmission line. It has a rectangular cross section ($16 \times 12.5 \text{ mm}^2$) and is constructed of two stainless steel conductors laminated to an epoxy core. It is available in various configurations with different lengths and numbers of segments. Segmented probes provide the opportunity for real-time, remote soil water monitoring, and graphical data presentation similar to capacitance probes.

Strengths and weaknesses of the technique are detailed in Table 1. An advantage of the TDR devices is that the determination of the travel time excludes the influence of low-frequency components of the electric pulse; hence systems employing TDR are relatively less sensitive to interferences of soil temperature, salinity, and clay content and type than are capacitance systems. A universal calibration for TDR probes for a wide range of soils has been developed, based on a laboratory-developed empirical relationship between the soil dielectric constant and the volumetric water content.^[21] However, similar to the other indirect devices, improved data accuracy will be achieved with site-specific calibration. Other positives are similar to those of the capacitance devices, given above, including the potential for automated water content profile determinations. Negatives are cost and as with capacitance, the smaller sphere of influence of TDR (than NMM) and associated problems given above.

CONCLUSION

The more modern techniques of capacitance and TDR, if used within a reasonable range of restrictions, provide attractive benefits over the other two techniques reviewed. With both capacitance and TDR, an attraction is the ability to automate the collection of remote (datalogger and telemetry), essentially continuous soil water data to 2 m depth. However, their small zone of influence necessitates very careful installation, and data collection should be restricted to non-swelling soil, or wetter, non- or minimally cracked soil to avoid problems with air gaps around capacitance access tubes and TDR probes, with resultant poor data. Neutron probes provide the best available method for repeated measurement of soil profile volumetric water content,^[6] have the largest zone of influence, and can access depths far greater than the other two indirect techniques. However, operational restrictions, perceived health fears from radioactive materials, and their inability to provide *in situ* automatic measurements (making them labor intensive) make them unattractive to some users.

Abstract

The least limiting water range (LLWR) has been developed as an index of the soil structural quality. The LLWR was defined as the region bounded by the upper and lower soil water content over which water, oxygen, and mechanical resistance become major limitations for root growth. Thus, it combines the effects of critical soil physical properties on biological processes into a single variable. Studies showed LLWR was related to shoot and roots growth and crop production. It also was effective to identify loss of soil quality caused by compaction due to animal trampling, tillage practices, and wheel traffic. The LLWR associated with measurements of microbiological processes rates may help predict the efficiency of different management systems to recover the quality of degraded soils.

INTRODUCTION

Soil quality evaluation should underline the importance of both intrinsic and dynamic soil properties and processes that have the potential to limit plant growth and development. The rates of many biological processes in plants vary with soil water content in a curvilinear manner, with slower rates at both low and high water contents. At low water content, the rates of these processes may be limited by the availability of water, soil strength, and accessibility of substrates or nutrients. At high water contents, the rates are generally limited by inadequate aeration. Thus, two important indicators of soil quality are the soil's ability to store water between rainfall and/or irrigation events and soil strength. The latter is essential for anchoring plants but can limit root growth if soil

strength becomes too high due to compaction caused by wheel traffic or natural reconsolidation.

To help quantify improvement or degradation of the soil physical properties, an index of the soil structural quality known as the least limiting water range (LLWR) has been developed. This index is soil specific and varies with texture or organic matter. It also varies with soil horizons as well as profile depth but collectively help describe effects of soil water content on many biological processes in soils. In addition, it has been recognized that LLWR combines the effects of critical soil physical properties on biological processes into a single variable.

One way to characterize the shape of a LLWR curve is by the horizontal spread between the upper and lower limits, i.e., the range in water contents at which the rate of a specific process is proportional to the maximum rate.

Under similar environmental conditions (e.g., temperature or rainfall/irrigation regimes), LLWR curve shape reflects the impact of soil structure on different biological properties and processes. Initially, the focus was on a non-limiting water range for plant growth. The LLWR concept was extended to evaluate this water content range as an index of structural soil quality. The concept of limiting water ranges for microbiological processes was also explored. Although the criteria for predicting upper and lower limits of LLWR for processes such as net nitrogen (N) mineralization or carbon dioxide (CO₂) emissions are not as well defined as those for plant growth, experimental measurement of the limits is more easily accomplished. The LLWR was combined with the SoilFlex model. This new model allows for predictions of changes in LLWR due to compaction caused by agricultural machines, and thus in soil conditions for plants growth.

The LLWR was defined as the region bounded by the upper and lower soil water content over which water, oxygen, and mechanical resistance become major limitations for root growth. LLWR is delimited by the supply of oxygen to the roots at the wet end, and the combined effects of water supply to the roots and mechanical resistance to root growth at the dry end. As soils become more dense, the LLWR becomes narrower, with mechanical resistance more commonly becoming the limitation at the dry end and poor aeration at the wet end.

METHODOLOGY AND APPLICATIONS

To construct the LLWR index, soil water contents (θ) at the critical limits of matric potential, soil strength, and air-filled porosity must be known for the range of soil bulk densities (ρ_b) likely to occur under the field conditions being evaluated.^[1]

Critical limits for LLWR have been defined as: 1) matric potential at field capacity (at either -10 kPa or -33 kPa) and permanent wilting point (-1500 kPa water potential); 2) air-filled porosity of less than 10%; and 3) soil strength >2.0 MPa.^[1–3] Water contents are then determined at the critical limits. For each soil sample, values of water contents at field capacity (θ_{FC}) and permanent wilting point (θ_{WP}) are measured directly or obtained from the water release curve (WRC, θ vs. ψ). Water content corresponding to 10% air-filled porosity (θ_{AP}) is calculated from the total porosity values. Water content corresponding to soil strength >2.0 MPa (θ_{SS}) is calculated from the relationship between soil strength, as measured by cone index, ρ_b and θ , assuming root penetration becomes negligible after cone penetrometer resistance exceeds 2 MPa. This relationship is known as soil resistance curve (SRC). Values of θ_{FC} , θ_{WP} , and θ_{SS} may also be estimated from pedotransfer functions.^[2]

Undisturbed soil samples are used to determine the functional relationships. Therefore, one of the most crucial

steps is sample collection, because to be meaningful, the variation of soil structural conditions, expressed by the soil bulk density, must be quantified to accurately model WRC and SRC. More details about models and statistical procedures used to obtain the WRC and SRC have been published.^[1,2] Once the functional relationships have been defined, the LLWR computation is carried out for each undisturbed soil sample as illustrated in Fig. 1.

The range defined by water content at field capacity (θ_{FC}) in the upper limit (Fig. 1A) and water content at permanent wilting point (θ_{WP}) in the lower limit (Fig. 1C) characterizes the traditional concept of available water capacity (AWC), which is widely used in soil science, ecophysiology, and irrigation. The AWC concept focuses on the functional relationship water content–water potential (θ – ψ) as a limiting physical factor for plant growth but as the oxygen diffusion rate in soil decreases, root growth can decrease even with elevated values of θ in the soil. In that situation, further soil drying is necessary to reach an appropriate aeration level. Similarly, in dry soils, soil strength may reach a limiting value before θ reaches the permanent wilting point.

Estimates of soil water content at upper critical aeration levels (θ_{AP}) are obtained from the relationship air-filled porosity–water content (AP– θ ; Fig. 1B). A simple approach involves the subtraction of a critical value of air-filled porosity [usually $0.10 \text{ cm}^3/\text{cm}^3$ (i.e., 10%)] from total soil porosity.

In soils with degraded structure, the wet end of the LLWR is commonly determined by θ_{AP} instead of θ_{FC} . In these cases, at θ_{FC} , plant growth is theoretically conditioned by restricted O₂ diffusion in the soil. The air-filled porosity is strongly dependent on soil structural, being linear and negatively related with ρ_b . At the dry end, depending on soil structural conditions, θ_{WP} may be substituted by θ_{SS} , which is calculated from the SRC (Fig. 1D). Water contents at the critical limits for a soil sample with $\rho_b = 1.27 \text{ g cm}^{-3}$ are shown in Fig. 1E.

Fig. 2, which illustrates the LLWR delimitation for a set of soil samples, shows that θ_{AP} substitutes θ_{FC} at $\rho_b = 1.35 \text{ g cm}^{-3}$, while θ_{SS} substitutes θ_{WP} starting from values $\rho_b = 1.37 \text{ g cm}^{-3}$. For this condition, LLWR is strongly reduced until reaching a value of 0. The maximum LLWR value coincides with the AWC range in this case.

The LLWR is zero when water content values at both the wet and dry end are numerically the same. The value of ρ_b at which LLWR = 0 is defined as the critical bulk density for that specific soil (ρ_{bc}).^[1] For the soil illustrated in Fig. 2, LLWR is zero when $\rho_{bc} = 1.55 \text{ g cm}^{-3}$. At this ρ_b value, plant growth is severely restricted by inadequate aeration and excessive soil strength. It has been demonstrated that corn shoot growth rate was correlated with the LLWR^[4] and that LLWR is effective for quantifying effects of soil property changes on plant root growth.^[3,5] This finding was supported by other studies that showed LLWR was related to crop production.^[6–8] A decrease in LLWR means that

Fig. 1 Illustration of the critical values determination of water content at field capacity (θ_{FC} ; A), air-filled porosity (θ_{AP} ; B), wilting point (θ_{WP} ; C), and soil strength (θ_{SS} ; D), which define the upper and lower limits of the LLWR (E) for one soil sample (e.g., with $\rho_b = 1.27$ g cm⁻³).

plants are increasingly susceptible to water-related environmental stresses and that productivity might be reduced. As LLWR becomes narrower, the frequency that soil structure may contribute to limit moisture conditions becomes wider (i.e., the soil water content will more likely fall outside the LLWR affecting crop production).^[9]

Fig. 3 shows the variation in the LLWR with ρ_b (LLWR curve) for the same set of soil samples used to illustrate the LLWR delimitation in Fig. 2. The LLWR at each ρ_b is the difference between the upper and lower water content. The former is the drier θ of either θ_{FC} or θ_{AP} , and the latter is the wetter θ of either θ_{WP} or θ_{SS} .

Fig. 2 Water content (θ) variation with soil bulk density (ρ_b) at critical levels of field capacity (θ_{FC}), wilting point (θ_{WP}), air-filled porosity (θ_{AP}), and soil strength (θ_{SS}). Gray area represents the LLWR. ρ_{bc} is the critical soil bulk density.

Factors Affecting the LLWR and Management Strategies to Enhance the LLWR

The LLWR is mainly affected by texture, organic carbon content, and bulk density (probably the most important for a given soil). This would include increases in ρ_b caused by wheel traffic or animal trampling compaction as well as that arising from natural consolidation during drying of soils that are structurally unstable because of low organic matter and/or the type of clay minerals.^[10–12] Fig. 4 illustrates changes in the LLWR curves due to soil degradation caused by combination of loss of soil organic matter and increased soil bulk density due to tillage compared with native soil.^[13]

Management practices to enhance the LLWR would include: 1) tillage designed to reintroduce macro- and mesopores in compacted soil; 2) controlling wheel traffic (traffic lanes) thereby restricting subsequent compaction to

Fig. 3 Variation in the LLWR with soil bulk density (ρ_b).

Fig. 4 Variation of the LLWR with soil bulk density (ρ_b) for different soil management systems.

Source: Adapted from Benjamin & Karlen.^[13]

localized zones in field; 3) reducing axle load and using larger tires for decreasing compaction; 4) avoiding animal trampling on wet soils; and 5) making soil less susceptible to compaction and natural consolidation by increasing organic matter content. One strategy to accomplish the latter would be to increase the amount of transient or temporary organic cementing materials that are effective in increasing wet aggregate stability and resistance to compaction. This could be done for some soils by incorporating crops with fine roots and fungal hyphae or cover crops into the rotation, animal or green manure, or applying urban/industrial wastes with high carbon but low metal or other phytotoxic content.

Opportunities and Limitations of the LLWR

Some merits of using LLWR to quantify soil physical quality are:

- It integrates four static soil characteristics (aeration, field capacity, soil mechanical resistance, and permanent wilting point) into a single variable.
- It describes the integrated effects of those characteristics in a way that is readily understood by farmers and advisory personnel and provides a semiquantitative measure of soil and crop management effects on soil structure.
- The LLWR can be combined with temporal variation in soil water content to indicate the frequency that a structure-induced stress may be encountered by a growing crop in soil with a given LLWR under the prevailing water budget conditions (this is crucial because the impact of management-induced structural change on crops varies with climate). This information can also be used to help those using irrigation determine better target water content levels to reduce total water use and optimize irrigation scheduling.

- The LLWR may be used to differentiate soils on the basis of the sensitivity of N mineralization to variation in water content.^[14]
- The LLWR associated with measurements of C–CO₂ emissions from the soils may help predict the efficiency of management systems to sequester carbon into the soils.^[15]
- The LLWR combined with compaction models may estimate the impact of soil loading and soil physical conditions for root growth, such a case of the SoilFlex-LLWR model.^[16]

Research needed to address limitations and unexplored aspects of the LLWR approach should include:

- Dynamic soil characteristics, such as parameters describing transport of water or oxygen.
- The role of limiting soil resistance levels within the soil matrix and their impact on calculated LLWR values.
- Assessments of the relevance of LLWR in compacted soils with abundance of macropores. This may be important because root growth occurs mainly in those pores rather than in the soil matrix.
- Determining more practical methods for quantifying limiting values since this is very time consuming.
- Improving our understanding of how soil characteristics such as soil resistance and aeration affect LLWR.
- Defining how rates of physiological processes that have the greatest influence on yield are related to the extent of the LLWR values.
- Quantifying susceptibility of different crops to changes in the soil environment. Finally, although interactions between limiting characteristics (e.g., effect of reduced aeration on limiting values of soil resistance) could be accounted for within the LLWR concept, these interactions are not generally considered.

CONCLUSION

The LLWR is effective in identifying soil quality constraints in plant growth because of different tillage, traffic, animal trampling, and cropping systems. The LLWR is also effective in identifying similar constraints on microbial processes such as the net mineralization of N or the CO₂ emissions. Knowledge of the LLWR for a soil can help the farmers improve the growing conditions by scheduling irrigation as well as implementing remedial management practices.

Water Retention

Satish C. Gupta

Dong Wang

Department of Soil, Water, and Climate, University of Minnesota, St. Paul, Minnesota, U.S.A.

Abstract

Soil water retention refers to the mechanism and processes related to changes in soil water content and its energy status. The relationship between these two quantities is called the soil water retention characteristics curve. This entry outlines the methods of measuring soil water content and its energy levels, causes of potential energy in soil water and how it varies with soil texture, mathematical models for describing soil water retention characteristic curves, prediction of soil water retention from easily measurable soil properties, hysteresis in soil water retention, and the definition of plant-available water in soils.

INTRODUCTION

Soil water retention refers to the mechanisms and processes related to changes in soil water content vs. its energy status. There are two components in the soil water retention as follows: 1) the amount of water held in soil; and 2) the potential energy with which the water is held. The relationship between the amount of water and its potential energy is called the soil water retention characteristic curve (Fig. 1). The water retention characteristic curves are different for different soil types (Fig. 2). These differences are caused by the variation in soil particle-size distribution and their packing arrangement. Both these factors influence the soil water retention by affecting the pore-size distribution and the number of a given pore size in each size class.

BACKGROUND

The maximum amount of water held in a soil depends on the surface area of soil particles and the fraction of pores in a given volume of soil (porosity). The potential energy of the soil water, on the other hand, depends on the size distribution of the junction between pores. The junction between pores can be viewed as a small capillary tube, the radius of which determines the force needed to drain the pore (Fig. 3).

The energy with which the water is held in a capillary tube can be described by the following capillary rise equation (Fig. 4):

$$h = \frac{2\sigma}{\rho g r} \cos \theta \quad (1)$$

where h is the height of rise of water in a capillary tube, σ is the surface tension force of water, ρ is the density of

water, g is the acceleration due to gravity, r is the radius of the capillary tube, and θ is the contact angle of water with the capillary tube. The smaller the radius of a capillary tube, the greater is the rise in water height. Applying this principle to soil water retention, the smaller the radius of the junction between two pore cavities, the greater is the energy needed to drain the pore restricted by the pore junction.

The energy with which water is held in soil is also called the soil matrix potential energy or simply the soil matrix potential. Because of the analogy between the capillary tube and the junction between soil pores, this energy is also called the capillary potential energy or simply the capillary potential. There are several ways to measure the potential energy of the soil. These include the tensiometer and the thermocouple psychrometer. The tensiometer consists of a small ceramic cup that is connected to a PVC tube on which a measuring device (vacuum gauge or mercury manometer) is mounted for recording the potential energy (Fig. 5).

In field applications of tensiometers, the ceramic cup and the PVC tube are first filled with de-aired water and sealed with a cap. The tensiometer is then installed in the soil and allowed to reach equilibrium with soil water. The negative pressure at equilibrium corresponds to the energy with which water is held in a soil.

The thermocouple psychrometer (Fig. 6) measures the relative humidity (RH) of the soil air that is in equilibrium with liquid soil water and its solutes. In the thermocouple psychrometer, water is first condensed at the thermocouple junction and then allowed to evaporate. The rate of evaporation is controlled by the RH of the chamber that is in equilibrium with the potential energy of the soil water.^[1]

The water potential (ψ_w) is related to RH by the following relationship:

Fig. 1 The schematic representation of soil water retention characteristic curve.

$$\psi_w = \frac{RT}{M} \ln(RH) \quad (2)$$

where R is the ideal gas constant, T is the absolute temperature, and M is the molecular weight of soil solution (water and solutes). Tensiometers are useful for measuring soil matric potential from 0 to -80 kPa, whereas thermocouple psychrometers are effective for measuring soil water potential from -1500 kPa to air-dry soil conditions.

The quantity of water held in the soil is expressed as the mass of water per unit mass of soil or the volume of water per unit volume of soil. The standard method of measuring soil water is by the gravimetric approach. In this case, the wet soil sample is weighed both before and after oven drying at 105°C for 24 hours or to a constant weight. The loss of water per unit weight of soil or per unit volume of soil thus quantifies the amount of water in the soil. The other methods include the neutron probe, the gamma ray attenuation, the time domain reflectometry (TDR), and the heat dissipation unit. The neutron probe is based on the principle that a fast neutron, when released in soil, will collide with hydrogen atoms, thus resulting in slowed neutrons. Because most of the hydrogen atoms in soil are from water, the number of slowed neutron thus determines the amount of water in soil.^[2] Gamma ray attenuation is based on the principle that an increase in soil water will decrease the number of gamma particles passing through the soil and

Fig. 2 The water retention of five different textured soils.

Fig. 3 Height in rise of water in capillary tubes corresponding to various neck radii in a pore.

vice versa.^[3] TDR measures the dielectric constant of the moist soil. Because the dielectric constant of liquid water is 80 and that of the soil matrix is 4, changes in the soil dielectric constant reflect the changes in soil water content.^[4] The heat dissipation method works on the principle that at higher soil water content there is faster dissipation of heat and thus lower rise in soil temperature.^[5]

MODELS OF SOIL WATER RETENTION

In this entry, there are several methods available for estimating the water retention characteristics of soils. These methods are generally based on the premise that there exists some relationship between the soil water retention characteristics and the soil particle-size distribution, soil packing density, and soil organic matter content. These are either empirical or semiphenomenological. The empirical relationships are also called the “pedotransfer” functions. Among the semiphenomenological methods, the most notable is the method of Arya and Paris.^[6] The basis of this method is that the shape of the pore-size distribution curve is similar to the particle-size distribution curve. Then, it is a matter of translating the

Fig. 4 Relationship between water rise, surface tension, and capillary radius.

Fig. 5 The schematic representation of tensiometry for soil water potential measurement.

particles of a given size to the amount of water held by those particles and the particle size to a corresponding pore size:

$$V_i = \left(\frac{w_i}{\rho_s} \right) e \quad (3)$$

$$r_i = - \frac{\sigma \cos \theta \sqrt{6}}{\rho_g R_i \sqrt{e n_i^{(1-\alpha)}}} \quad (4)$$

where V_i and w_i are the pore volume and weight of i^{th} fraction, respectively; ρ_s is the particle density; e is the void ratio; r_i and R_i are the mean pore and particle radii of the i^{th} fraction, respectively; n_i is the number of particles in i^{th} fraction, and α is an empirical constant ranging in value from 1.35 to 1.40.

Fig. 6 The schematic representation of thermocouple psychrometer.

Pedotransfer Functions

The pedotransfer functions, or the empirical methods of predicting soil water retention characteristics, use the easily measurable soil properties such as particle-size distribution (sand, silt, and clay contents), bulk density, organic matter content, etc. as surrogates of water retention in soil.^[9] Using the measured database, an empirical equation that predicts the water retention at each soil matric potential is developed. Among the most widely used empirical methods of predicting water retention characteristic is the method proposed by Rawls and Brakensiek.^[10] This empirical method is based on water retention measurements of over 2000 soil horizons. In this method, the empirical relationships predict soil water content at 12 matric potentials (Table 1). The relationships are provided for three levels of input parameters. The first level assumes that the only inputs available are the percent sand, percent silt, percent clay, bulk density, and the organic matter content. The second level of relationships assumes that in addition to the input parameters for the first level of regression equation, the water content of the soil at -1500 kPa matric potential is also known. The third level of regression further assumes that the soil water content at -33 kPa soil matrix potential is also known. Over the years, the method has been modified and improved by the inclusions of additional data sets and/or other input variables.^[11–13]

Mathematical Description

Various mathematical functions have been used to describe the complete soil water retention characteristic curve. Notable among those are the functions suggested by Brooks and Corey^[14] and van Genuchten.^[15] The Brooks and Corey function is:

$$\Theta = \frac{\theta - \theta_r}{\theta_s - \theta_r} = \left(\frac{h_e}{h} \right)^{-b} \quad (5)$$

whereas the van Genuchten function is:

$$\Theta = [1 + \alpha(-h)^n]^{-m} \quad (6)$$

$$m = (1 - n^{-1}) \quad (7)$$

where θ is the normalized water content; θ_r is the residual water content; θ_s is the saturated water content; h is the apparent soil matric potential; h_e is the air-entry matric potential; and α , b , n , and m are constants for a given soil. Because of their mathematical superiority, these two functions have been widely used in many soils and hydrologic modeling studies. Pedotransfer functions have also been developed for predicting parameters of the Brooks and Corey and van Genuchten functions based on easily measurable soil properties such as percent sand, silt, clay, organic matter, and bulk density.^[11–13]

METHODS OF CHARACTERIZING SOIL WATER RETENTION

The measurement of soil water retention requires simultaneous determination of soil water content and potential. In the laboratory, the traditional methods of measuring soil water retention involve establishing a series of equilibrium between water in the soil sample and known potentials.^[16] Two of the most common methods that use

this principle are the hanging water column and the pressure plate apparatus. In case of hanging water column, an initially saturated soil sample placed on a ceramic plate is allowed to drain by gravity until there is no more drainage. The soil water content at equilibrium thus corresponds to the gravitational forces equivalent to the distance between the soil sample and the water reservoir. The pressure plate apparatus consists of a ceramic plate and a pressure chamber. The soil sample is placed on a

Fig. 7 Hysteresis in soil water retention.
Source: From Hillel.^[19]

ceramic plate; the plate and the soil sample are allowed to saturate overnight and then are desorbed by applying a known air pressure to the chamber. When no more water comes out of the soil sample, the sample is in equilibrium with the applied air pressure, and thus, the energy of the soil water is equivalent to the applied air pressure. The soil sample is taken out and its water content measured gravimetrically.

Soil water retention characteristics can also be characterized *in situ* using tensiometers and various water content measuring devices. A widely used approach is the instantaneous profile method where a flooded area is allowed to drain, and then the soil water content and matric potential are measured simultaneously using a neutron probe and tensiometers.^[17] Wang, Yates, and Ernst^[18] used a combination of small tensiometers and TDR probes to measure *in situ* water retention. In this setup, the authors used a tension infiltrometer as a source of water supply.

HYSTERESIS

For a given soil, the soil water retention characteristic curve varies depending on whether the curve was obtained by desorbing a saturated soil or by wetting a dry soil (Fig. 7).

This behavior in water retention characteristics is called the “hysteresis.” The main reason for the hysteresis is the so-called “ink-bottle” effect, which refers to narrow points of connection between large cavities of the adjoining pores (Fig. 8).

During drying, the water content in the soil is controlled by the narrow points between pores (Fig. 8A), whereas during wetting water retention is controlled by the widest point in the pore cavity (Fig. 8B). As a result of this, the soil at any given potential retains more water

Fig. 8 “Ink-bottle” effect on water imbibition (A) and drainage (B) in large soil pores.
Source: From Hillel.^[19]

while drying than wetting. The wetting and drying curves in Fig. 7 are called the primary curves, whereas the curves connecting the primary curves are called the scanning curves. Scanning curves define the path that a soil takes when switching from wetting to drying and vice versa.

PLANT-AVAILABLE WATER

From the plant growth perspective, two points on the soil water retention curve are significantly important. These are the water retention at soil matric potential of -33 kPa (field capacity water content) and the water retention at soil matric potential of -1500 kPa (permanent wilting point or PWP). The field capacity water content refers to soil water content after a saturated soil has been allowed to drain for 24–48 hours without any significant evaporation. Field measurements have shown that for most soils, the matric potential at field capacity water content corresponds to -33 kPa. If the water retention was measured on a disturbed soil, then the field capacity water content corresponds to a soil matric potential of -10 kPa. PWP refers to soil water content when plants fail to recover its turgidity on watering. Field measurements have shown that this water content corresponds to about -1500 kPa for most plants. Water retention between soil matric potentials of -33 and -1500 kPa is referred to as the available water for plant growth.

As expected, available water capacity of soil varies with soil texture (Table 2). Generally, medium texture soils have higher available water capacity than either the fine-textured or the coarse-textured soils. This is due to both relatively higher field capacity and lower PWP water content of medium texture soils than the coarse-textured or the fine-textured soils. In coarse-textured soil, water content at PWP is low but so is the water content at field capacity. In fine-textured soils, water content at field capacity is higher but so is the water content at PWP.

Table 2 Available water capacity of soils of various textural groups.

Soil texture	Available water (m ³ /m ³)
Clay	0.076

CONCLUSION

Soil water retention refers to the mechanism and processes related to changes in soil water content and its energy status. The relationship between these two quantities is called the soil water retention characteristics curve. This entry outlines the methods of measuring soil water content and its energy levels, causes of potential energy in soil water and how it varies with soil texture, mathematical models for describing soil water retention characteristic curves, the prediction of soil water retention from easily measurable soil properties, hysteresis in soil water retention, and the definition of plant-available water in soils.

Abstract

The definitions of the upper and lower limits of plant available water are difficult to establish because of water flow into and out of the root zone and because of incomplete extraction by sparse roots at the lower boundaries of the root zone. If the limits of plant available water cannot be measured, they can be estimated based on routinely measured soil properties. This entry presents a simple model that uses few parameters. The model can make it easier to approximate soil water limits in water balance simulation, irrigation scheduling, and watershed management.

INTRODUCTION

Accurately evaluating the available soil water reservoir is vital to developing optimum management for rain-fed crop production in marginally dry regions. Often there is a linear relationship between plant available water and yield^[1] and between plant available water and leaf growth, within limits.^[2] Phenology can be delayed due to preanthesis drought stress.^[2]

Two forces retain water in the soil: adhesion and cohesion. Adhesion is the attraction of water molecules to soil particles. Cohesion is the attraction of water molecules to each other. These two forces oppose the effect of gravity that removes soil water by drainage. The maximum storage of useful water to the plants depends on the equilibrium between soil water retention forces and gravity. Mostly, the minimum storage depends on the retention forces. There is some water that is held so tightly in the soil that the plants cannot extract (Fig. 1).

DEFINING THE LIMITS OF PLANT AVAILABLE WATER

We define potentially plant available water or potentially plant extractable water (θ_p) as the difference between the drained upper limit (θ_d) and the lower limit (θ_l). The drained upper limit is the highest, field-measured water content of a soil after thorough wetting and draining until drainage becomes practically negligible. The θ_d corresponds closely to water content at “field capacity” and to matric suction in the range of 10–33 kPa. The lower limit, θ_l , is the lowest, field-measured, volumetric water content

of a soil after plants stop extracting water due to premature death or dormancy as a result of water deficit. The lower limit corresponds closely to the water content at the “permanent wilting point” and to matric suction of 1.5 MPa. Potentially plant available water is similar across a wide range of soil textures (Fig. 2). The mean and standard deviation of field measured θ_p for a wide range of soils are shown in Table 1.

MEASURING THE LIMITS OF PLANT AVAILABLE WATER

The traditional approach to evaluating the limits of available water has been to measure the “permanent wilting point” and “field capacity” of soil samples removed from the field through use of pressure chambers. Usually, soil water contents are measured at suctions of 1.5 MPa for the wilting point and 10–33 kPa for field capacity. Samples are taken from the soil at various depths to the measured or estimated rooting depth. The difference between the upper and lower limits of availability is summed over the rooting depth to determine the total potentially plant available water.

Several criticisms have been made of the above rather static definitions of available soil water limits. Water above the upper limit can be taken up while drainage is occurring. Plant growth can be retarded before the lower limit is reached. Water extraction by roots may continue beyond the 1.5 MPa range in some instances. Where root density is low, especially in deep soils, it is difficult to separate the effects of root distribution from the effect of water flow through the soil on available water.

Fig. 1 Schematic of water in soil pores at three water contents: (A) saturation (entrapped air bubbles persist), (B) drained upper limit (larger pores empty, menisci form between soil particles), and (C) lower limit (thin films around soil particles).

Fig. 2 Potentially extractable soil water $\theta_d - \theta_l$ is similar among soils with a wide variety in texture. Heavy textured soils have higher proportion of smaller pores, therefore both the upper (θ_d) and the lower limit (θ_l) are higher than in light textured soils.

FIELD MEASUREMENT OF THE UPPER LIMIT

The drained upper limit is a necessary input in water balance models. The “tipping bucket” approach in water balance models such as in DSSAT^[4] can be sensitive to the value chosen for θ_d .^[5] Because water can be taken up by plants while drainage is occurring, the drained upper limit is not always the appropriate upper limit of soil water availability. Therefore, it is necessary to measure or reasonably estimate the drainage rates while they are significant.

Table 1 Potentially plant available water for soils of different texture as measured in the field. The values range from a minimum of $8.0 \pm 3.1\%$ for sands to 14.8% for just one observation for the silt. The mean plant available water values for the remaining textural classes are within a narrow range of only $11.0\text{--}14.3\%$.

Texture	No. of samples	Mean and standard deviation for θ_p
		(volume percent)
Sand	76	8.0 ± 3.1
Loamy sand	7	12.9 ± 3.6
Sandy loam	31	13.2 ± 2.2
Loam	51	13.6 ± 3.0
Silt loam	83	14.3 ± 3.3
Silt	1	14.8
Silty clay loam	53	13.0 ± 2.1
Clay loam	41	12.5 ± 3.2
Sandy clay loam	24	11.0 ± 3.5
Sandy clay	0	
Silty clay	31	13.4 ± 3.0
Clay	3	12.9 ± 3.6

Seven hundred and two planted on a silt loam soil (Entic Haplustoll) in Cordoba, Argentina, during the 1992–1993 growing season. The dashed line indicates the field measured drained upper limit, and the solid heavy line indicates water content measured in the laboratory at 1.5 MPa suction.

Source: From Dardanelli, Bachmeier, et al.^[7]

There are functions to estimate drainage flux that are relatively simple to evaluate from field data.^[6]

FIELD MEASUREMENT OF THE LOWER LIMIT

Field measurements of the lower limit of water availability are more difficult than measuring the upper limit because root growth dynamics are different between and within crops and also because conditions for the lower limit may not often naturally occur.

The best value for the lower limit is obtained when crops reach their maximum vegetative size without stress and then grow on stored soil water until plants are visibly severely distressed. Because leaf senescence and natural death of many crops occur at maturity, it is important that plants have undergone premature severe stress. On the other hand, any stress that causes a reduction in root growth

before establishment of a “normal” rooting profile can cause incomplete root water extraction. Nutrient, drought, and aeration stresses, as well as chemical boundaries in soil, may restrict root growth and rooting depth.

Crop species and cultivars within a species may exhibit differing final water content values at crop maturity. Information on the lowest measured water content for several crops experiencing terminal drought is in Fig. 3. Results indicate that this soil is uniform with depth and the 1.5 MPa suction was quite close to the lowest measured water content when the crop had sufficient time and rooting density to remove the water down to the θ_l . The true θ_l was reached in the 20–80 cm depth for all crop situations but was not obtained below that depth for a short maturity soybean. In contrast, the long season sunflower Contiflor 3 extracted water to the θ_l to a depth of about 260 cm.

ESTIMATING THE LIMITS OF PLANT AVAILABLE WATER

When the cost and time of primary data collection is prohibitive, it is necessary to estimate reasonable values for the limits of the soil water reservoir. Many studies have found statistical relationships between plant available water and one or more soil properties such as texture, organic matter content, coarse fragment content, and bulk density.^[8–11] To achieve a good fit, statistical models can be very complex and may behave erratically. There are many soil properties that are related to the water limits. The more predictors there are in a model, the more specific the model becomes to a particular data set and its generality is being lost. Also, the additional data required to use a complex model are not always available.

To derive a simple model, we used a database of field measured soil water limits.^[3] The database contained 401 soil samples from 15 states of the United States. Seven soil orders were represented, but over 60% of the soils were Mollisols or Alfisols. Histosols, Oxisols, and Spodosols were not represented. There were few data from the midwest and southeast United States. The fact that these regions experience frequent precipitation during the crop growing season precludes the casual collection of field-measured lower limit.

We selected the gravimetric drained upper limit (w_d) as the first dependent variable to estimate, to make the model sensitive to bulk density, and to avoid the error associated with the measurement of bulk density. The model of w_d was

$$w_d = 0.186(\text{sand/clay})^{-0.141} \quad (1)$$

where w_d is the gravimetric water content and “sand” and “clay” are percent sand and clay. Then θ_d can be calculated from

$$\theta_d = w_d \rho_b / \rho_w \quad (2)$$

where θ_d is the volumetric water content, ρ_b is the soil bulk density, and ρ_w is the density of water.

The second dependent variable that we estimated was θ_p , the volumetric, potentially plant extractable water content. We picked sand content as the independent variable once we realized that θ_p is approximately the same across soils, except for soils with high sand content.^[3] The model was

$$\theta_p = 0.132 - 2.5 \times 10^{-6} e^{0.105 \text{ sand}} \quad (3)$$

where 0.132 is the mean θ_p for soils with less than 65% sand.

Then, we modified the estimates of θ_d and θ_l for coarse fragment content (particles larger than 2 mm in diameter) and for unusually high organic C content. The equations were tested with a limited independent data set with good results.^[12]

The θ_l can be calculated as the difference between θ_d and θ_p . The plant extractable water for the soil profile can be calculated as the product of θ_p times soil depth, in units of soil depth. If a profile consists of layers of different composition, then the plant extractable water of the profile is calculated as the sum of the extractable water of each layer. It is important to know the rooting depth and the root density of the crop. The concept of plant extractable water is meaningful only in that depth where roots are dense enough to effectively extract water.

PLANT AVAILABLE WATER AND SOIL-WATER MANAGEMENT

Irrigation scheduling is an obvious application of plant available water information. Through proper irrigation scheduling, it should be possible to apply only the water that matches the evapotranspiration or to meet some other desired criteria.^[13,14] A rule of thumb is that irrigation is needed when the soil water content drops to 50% of potentially extractable soil water for crops such as alfalfa, corn, and spring grains.^[13] However, reduction in growth has been observed at a water content as low as 85% of potentially extractable soil water, in sandy soils.^[2]

Precision agriculture is the management of spatial and temporal variability in all aspects of agricultural production to improve crop performance and environmental quality.^[15] Ideal management variables are those with high spatial dependence and low temporal variance. Plant available water probably has high spatial dependence and high temporal variance, so it is not an ideal candidate for precision management, yet there are two possibilities for precision water management that are related to plant available water: variable rate irrigation and matching agronomic inputs to plant available water defined by soil and/or landscape properties.

Variable sprinkler irrigation systems exist, usually coupled with chemigation. Limited experience so far indicates that the benefits of such systems have not

been fully realized. The potential usefulness of matching agronomic inputs to plant available water increases with spatial variability in plant available water. Mapping small-scale variability is expensive, so perhaps a more viable approach is to map relief or some landscape attribute that is indirectly related to plant available water.^[15]

Tillage seems an important factor in the conservation of plant available water in dryland production. In one case, no-tillage resulted in improved soil water conservation during fallow compared to stubble mulch tillage.^[16] No-tillage afforded substantially higher soil water contents during planting of the crop after fallow. This could be because no-tillage results in less evaporation.

CONCLUSION

The definitions of the upper and lower limits of plant available water are difficult to establish because of water flow into and out of the root zone and because of incomplete extraction by sparse roots at the lower boundaries of the root zone. Pressure extraction equipment used on soil samples removed from a field often does not provide reliable estimates of the limits of water availability when comparing it to observations in the field. Therefore, for accurate soil water balance, it is important to measure the upper and lower limits in the field.

If the limits of plant available water cannot be measured, they can be estimated based on routinely measured soil properties. We present a simple model that uses few parameters. The model can make it easier to approximate soil water limits in water balance simulation, irrigation scheduling, and watershed management. A challenge will be to manage the spatial and temporal variability in plant available water in precision agriculture systems to improve crop performance and environmental quality.

Abstract

Relative amounts of hydrophilic and hydrophobic constituents in the structure of the soil determine soil water repellency or wettability. Changes in the spatial distribution of hydrophilic and hydrophobic soil constituents, in their mutual interactions, and in their interactions with water change soil water repellency. Some degree of water repellency is favorable to the conservation and to the productivity of the soil. However, remarkable production and soil losses occur in severely water repellent soils. In addition, water repellency can be a major concern for the contamination of groundwater with pollutants not retained on hydrophobic soil surfaces. Therefore, preventive and remedial management practices are needed for alleviating problems of water repellent soils.

INTRODUCTION

Soil water repellency is the inability of the soil to become wet and is the opposite of wettability. Soil and water quality and crop yields can be strongly affected by soil water repellency through decreased moisture availability to plants, accelerated soil erosion, and nutrient and pesticide transport. Soil water repellency is determined to a large extent by the hydrophobicity (repulsion for water) and the hydrophilicity (affinity for water) of soil surfaces (Fig. 1). The liquid–solid contact angle and the wetting time tend to zero on hydrophilic surfaces, so that water molecules lay parallel to hydrophilic surfaces. The liquid–solid contact angle increases toward 180° with an increase in hydrophobicity. Soil water repellency can be quantified by measuring the contact angle between soil surfaces and water. Otherwise, water repellency can be expressed by the rate of water entry in unsaturated soil. Amount, sizes, geometry, orientation, connectivity of soil pores, and hydrophobicity of pore walls affect soil water repellency. Water repellency is a dynamic soil property that varies with time following the soil structural and water potential changes during wetting and drying processes. “Actual” and “potential” water repellency characterize the wetting behavior of the soil because soils may be wettable when moist and be highly water repellent when dry.^[1] Water repellency shows a wide spatial variability changing with landscape position at a topographic scale, with soil depth

and area at a field scale, and along pore surfaces at a microscale. In general, soils are not completely water repellent, but their wetting rate can be relatively slow. Subcritical water repellency is the term used for soils with limited wettability.^[2]

EXTENT AND ORIGIN

Soil water repellency may affect soils of any texture in any climatic conditions around the world. From Australia to Canada, Egypt, India, the Netherlands, Japan, Spain, Colombia, New Zealand, South Africa, Turkey, Taiwan, Great Britain, Chile, and Mali among many other countries, problems of soil water repellency have concerned agricultural, range, and forest lands.^[3,4] Wide spread occurrence of water repellency has been recorded also in the United States from Oregon to Florida, Wisconsin, Arizona, California, New Mexico, Colorado, Nevada, and Michigan.^[3,4] Major sources of water repellency are organic compounds bound to soil minerals, or organic coatings as well as organic debris including hydrophobic particulate organic matter in the sand fraction and hydrophobic fine-structured organic particles in the clay fraction.^[5] Soil water repellency is not related to a specific size fraction. However, sandy soils are more susceptible to hydrophobic coating by organic matter than soils containing ≥15–20% clay minerals that have highly hydrophilic

Fig. 1 Water drops on a solid surface. The hydrophobicity of the surface and the liquid–solid contact angle decrease from (A) to (D).

specific surface area.^[6] Organic matter may affect wettability by: 1) increasing the hydrophobic surface and/or 2) stabilizing the soil pores.^[7] The stabilization of soil pores is likely to prevail in clay soils. The origin and the degree of decomposition of the organic matter affect soil water repellency.^[8] Fungal growth and partial alteration of plant organic matter are favorable to the production of hydrophobic compounds. Fire-induced water repellency results from burning of organic matter. During fires, soil particles and aggregates can be coated through the deposition of volatilized compounds. Fires with temperatures from 170°C to 280°C at the mineral soil surface are optimal to produce hydrophobic depositions in subsurface cooler layers.^[9] Water repellency changes with the type and configuration of organic matter. Amphipathic molecules are likely to be involved in temporal changes of wettability. Organic polar groups exposed in wet soils may mutually interact in dry water repellent soils. Hydrophobic organic compounds, such as lipids, can cause severe water repellency even in small amounts in combination with hydrophilic organic compounds. The extraction of both water repellent and water-soluble organic fractions can effectively increase the wettability of the soil.^[10] No specific hydrophobic substances have been detected in fire-induced organic coatings.^[9] In most soils, hydrophilic organic compounds dominate, and they can decrease or increase soil water repellency. Highly hydrophilic molecules such as polysaccharides can decrease soil rehydration rate and wettability.^[11,12] Organic compounds with polar groups interacting with clay minerals can limit clay swelling and increase pore stability. Strengthening of soil pores can increase soil water repellency because aggregate slaking is prevented and water cannot enter quickly into the soil as through planes of failure created during aggregate collapse in slaked soil.^[13]

PRACTICAL IMPLICATIONS

Increased overland flow results from decreased infiltration in water repellent soils. Splash and rill erosions may be severe in water repellent soils especially in the case of fire-induced water repellency where runoff is favored by the lack of vegetation and pore plugging by ash. A water repellent fire-induced subsurface layer can slow down water percolation. When the surface layer becomes saturated, failure tends to occur at the boundary between water

repellent and wettable layers, and the soil may slide down the slope.^[9] Similar erosion losses have been recorded on unburnt water repellent sloping soils.^[14] Water repellent soils tend to be drier than wettable soils with the reductions of crop growth. Delayed germination in drier areas of pasture and crops favors wind erosion and increases weed competition. Crop and pasture production is reduced by water repellency on 5 million ha in Australia.^[15] Preferential flow may cause nutrient losses and contamination of groundwater with fertilizers and pesticides percolating rapidly through wettable fingers in water repellent soils (Table 1).

On the other hand, water repellency can reduce wetting rates and consequent stresses on soil aggregates increasing wet aggregate stability. Subcritical water repellency creates the most favorable conditions for structural stability and plant growth.^[16]

The spatial variability of water repellency needs to be taken into account in evaluating soil wettability of the soil in the field. Presence of thin water repellent layers in the profile may little contribute to the entire water repellency when they underlie hydrophilic layers, and the depth of the water above them creates a pressure head exceeding the breakthrough pressure head. Animal burrows, root channels, cracks, and hydrophilic soil pockets can reduce the effects of water repellency on runoff because they allow fingered water infiltration.^[14]

High water repellency has practical applications in water harvesting. Techniques for coating soil particles with water repellent films have been developed.^[3]

MANAGEMENT OF WATER REPELLENT SOILS

Forage species adapted to water repellent soils have been selected for increasing the productivity of water repellent pastures.^[15] Shrubs and trees can be productive in water repellent soils because, once established, they can uptake nutrients and water from the subsoil. Furrow sowing in moist soil below the dry surface or trench planting of

Prevention by

1. Regular use of prescribed fires in forests
2. Frequent irrigation of crops and turfs

seedlings in wettable subsurface layers may help crop establishment. Furrow sowing and trench planting take advantage of the remaining strips of water repellent soil to harvest water, which can flow to the seeds. Narrow furrows with mulching, possibly refilled after plant establishment, are convenient in climates with wet periods to prevent excess of water in the furrows, excess of preferential flow, and consequent nutrient and pesticide leaching (Table 2).

Fire-induced water repellency can be prevented by regular use of prescribed fires that minimizes soil heating. Soil chemical stabilizers and wetting agents, although expensive, have been locally applied to reduce post-fire erosion, whereas mechanical techniques such as disking are generally impractical in sloping and stony lands.^[9] The prevention of water repellency in turfgrass systems can be achieved by maintaining high soil moisture and fertility with frequent irrigations and fertilizer applications. The alleviation of water repellency in intensively managed turfs can be obtained by the applications of surfactants. In water repellent cropped fields or pastures, surfactants may be applied in bands in the furrows where seeds are planted to improve wetting. Especially non-ionic formulations of surfactants can be effective against soil water repellency without causing phytotoxic secondary effects.^[17]

Clay minerals have been successfully added to amend water repellent sandy soils. Kaolinite may be preferable because kaolin crystals spread out covering the hydrophobic surfaces of soil particles and aggregates, whereas smectitic clays tend to aggregate upon drying.^[18] Added clays reduce soil water repellency, increase soil moisture retention, and may also increase soil fertility by improving the cation exchange capacity. Clays need to be evenly incorporated in the water repellent soil for best results. Claying has improved the productivity of 37,000 ha in South Australia, in general doubling crop yields, increasing pasture quality and forage yields from 400 to >3000 kg ha⁻¹.^[19] Enhanced microbial degradation of hydrophobic materials may contribute to the improvement of wettability by clay additions. Liming may alleviate water repellency especially when fungal hydrophobic

compounds are prevalent by shifting the composition of the microbial population of the soil.

No-tillage and mulching can reduce soil drying, while old roots and more abundant faunal macropores can provide channels for water infiltration. Moreover, no-till systems can reduce risks of nutrient leaching and groundwater contamination through organic matter retention and microbial degradation of pesticides.^[15]

CONCLUSION

Relative amounts of hydrophilic and hydrophobic constituents in the structure of the soil determine soil water repellency or wettability. Changes in the spatial distribution of hydrophilic and hydrophobic soil constituents, in their mutual interactions, and in their interactions with water change soil water repellency. Some degree of water repellency is favorable to the conservation and to the productivity of the soil. However, remarkable production and soil losses occur in severely water repellent soils. In addition, water repellency can be a major concern for the contamination of groundwater with pollutants not retained on hydrophobic soil surfaces. Therefore, preventive and remedial management practices are needed for alleviating problems of water repellent soils.

Abstract

Soils are open systems with natural and human-induced complexities. Water is an important change agent and state variable in soil systems that interact over a broad range of space-time scales. Thus, soil and water management must be understood and practiced in the appropriate context of the landscape and hydrologic system.

THE HYDROLOGIC CYCLE

The hydrologic cycle is defined as the movement of water from the ocean and other sources into the atmosphere, then to the land surface, yielding flow and storage over and through soils and other geologic media to groundwater aquifers, streams, and rivers, and finally returning to the ocean. The water's physical state (liquid, solid, or vapor), energy state, and chemical composition (dissolved constituents) may be altered at various points along its journey through the cycle. Its particular state as it enters, transits, and exits, the soil system plays an important role in the physical, chemical, and biological processes that occur in the soil, including their rates. The hydrologic processes of a particular system may vary significantly in space and time, and much of the local variability is linked to the global climate system. Various aspects of the global climate are not well understood (and poorly predicted), but multidisciplinary and international efforts are aimed at improving this aspect of the science and policy.^[1]

The hydrologic cycle may be considered a closed system (in terms of conservation of mass) that encompasses open systems of soils (Fig. 1). Water moves into and out of a soil system in multiple directions, even though one may tend to think of (vertical) surface infiltration and evapotranspiration dominating the water balance. Water is also stored in the soil–plant system for various periods of time. The residence time of this water and its constituents is important for biochemical transformations, and the rate of water flow affects the transport of key chemicals within and through soils.

A watershed, in turn, is defined as a region of land that contributes to a river system or reservoir. It is a compartment of the full hydrologic cycle that may cover an area of a few hectares to many thousands of square kilometers.

Water flow and storage within a watershed can be related to its geology, landscape topography, and soil hydraulic properties. The surface topography generally determines the energy gradients for movement of incipient precipitation over and through the ground. The flow paths may be confounded by complex geology and development of the parent material, along with the partitioning of water between infiltration and runoff based on the soil hydraulic properties. The location of a soil system within a watershed will determine the soil physical properties and the potential for inflow and outflow of water (e.g., inflow of water from upland areas, exchange of soil water with shallow groundwater, and the degree of natural and human-induced drainage). The landscape position also affects the chemical status of the soil that controls processes such as plant growth and biological toxicity. Thus, the location of an open soil system within a watershed is paramount to how the soil system and processes of interest should be managed.

NATURAL VARIABILITY

Soil and water management on a watershed scale must consider the high degree of variability in soils and related factors within a watershed. Soil formation and development have been studied extensively, and the foundational work of Jenny^[2] qualitatively identified five factors of soil formation: parent material, topography, climate, biota, and time. Additional factors include human activities (see below). While some soil attributes vary slowly compared with the time period of interest, the dynamics of other attributes cannot be ignored. From a practical point of view, some fraction of the natural variability cannot be explained; thus predictions must be assigned some level

Fig. 1 A schematic view of open soil systems in the context of a watershed and hydrological cycle: upland forests, rangelands, dry-land cropping systems, and pivot- and furrow-irrigated cropping systems.

of uncertainty that the producers, land managers, or other stakeholders must accept.

SCALE: MOVING UP FROM POINT TO PLOT TO FIELD TO WATERSHED

Various properties of a soil may be measured or characterized on a small scale that is essentially a point in comparison with the variables or processes of interest. Many research studies in agronomy have been performed on experimental plots, typically on the order of a few tens of square meters. One of the most important challenges in the earth, soil, and agronomic sciences is transferring information from one spatial scale to another (i.e., scaling) for management purposes. There are two problems with scaling within a watershed: aggregation of land units (upscaling) and disaggregation to individual land unit responses (downscaling). Upscaling provides important information about cumulative (off-site) effects on water quantity and quality over a watershed, while downscaling provides the necessary information to prescribe spatial management and predict on-site effects. The theoretical challenge involves both statistical scaling—based on measurements over a broad range of scales—and process-based, spatially distributed prediction. By addressing these issues and developing new computational methods to combine with measurements on real landscapes, practical prediction tools (with estimated uncertainties) for land management at appropriate space and time scales can be provided.

MANAGEMENT EFFECTS

The effects of historical land management must be borne in mind when devising management plans on a large scale. Most of the land masses of the earth have been impacted to some degree by human land management practices. These include burning and clearing for agriculture, forestry, water diversion and storage, urbanization, transportation infrastructure, mining, and various agricultural and industrial land uses. In agriculture, widespread irrigation and drainage have converted deserts and wetlands, respectively, into croplands. Overirrigation and lack of adequate drainage have resulted in salinity problems and waterlogging. Less dramatic, yet significant, impacts on rainfed lands can be related to tillage practices, crop rotation, and grazing rates.

Advances in satellite-based remote sensing and geographical positioning have led to high-resolution mapping of landscape properties and state variables. This can be applied to spatial soil water management practices in the hope that average agricultural production will increase while adverse environmental effects decrease. For example, the practice of varying agronomic input rates within a farm field, known as “precision agriculture,” touts such technology-dependent promises (see van Schilfgaarde^[3]; www.precision.agri.umn.edu). Although the technology has improved dramatically, there is a need for improved scientific prediction to aid management decisions. Furthermore, the long-term feedback between landscape variability and spatial management will need to be addressed.

STRATEGY

A strategy for soil and water management should be based on a watershed approach to account for the various inputs that control the soil system as well as to determine off-site impacts of the management practices used. The watershed approach recognizes multiple land uses within a given watershed such that management practices on one land area affect another. These interactions in space and time have been explored in some situations but generally require further consideration.

Potential strategies are discussed below for croplands (irrigated and rainfed), rangelands, and forests. The soil scientist must recognize all important (or potentially important) uses and devise a means for accommodating all existing and planned uses. Diverse uses are likely to interact and often cause conflict. This requires developing technically sound alternative proposals, but even more importantly, engaging in conflict resolution by involving all interested parties in meaningful negotiation. Thus, community acceptance is added to the physical problem.

Irrigated Croplands

Some 37% of global crop production comes from the 12% of arable land that is irrigated, much of it in arid climates. Irrigation uses a large portion of available water resources and consequently may deprive cities or industries of water resources. Reduced water in streams may affect fish and wildlife adversely, and return flow from irrigation always degrades the quality of the remaining water resource. Thus, the strategy in managing irrigated agriculture must be to find a balance between crop production and other uses. One component of such a strategy may be to increase irrigation efficiency so as to make more water available for other purposes; another is to concentrate polluting salts in a smaller volume of drainage water or return flow to simplify separate disposal. In a report on agricultural salinity, van Schilfgaarde^[4] addressed the question looming over irrigated agriculture: "Is it sustainable?" Due to the inevitable degradation of water quality in streams and terminal basins and the associated costs, the question of sustainability was restated as, "Are we prepared to maintain irrigated agriculture indefinitely?"

Rainfed Croplands

Many rainfed agricultural areas have been (or need to be) drained to enhance production. Reducing wetlands, however, deprives migrating birds of nesting and resting places, disturbing the natural order. Fish and wildlife specialists need to work with farm interests to find a balance. This may include the preservation of some wetlands, restoring fish habitat in streams and drainage channels, and using crop rotations that encourage diverse fauna. Income from hunting may offset possible losses from reduced crop

production, and ecological criteria may supersede economic benefits.

Rangelands

Rangelands serve many functions: They store snow and modulate runoff to enhance stream flow, they support wildlife and diverse flora, and of course they provide grazing lands for cattle, among others. Overgrazing can affect the vegetation, hydrology, and soil erosion. Cattle on stream banks may also cause erosion and pollute the water. A strategy for sustainable management goes beyond providing the maximum number of grazing days for a herd of cattle.

Forests

Issues of forest management are not to be overshadowed by the above issues for agricultural lands. A disadvantage in terms of soil water management is that forest soils tend to be overshadowed by the trees—literally and figuratively. (See www.soilslab.cfr.washington.edu/S-7/HistForSoilNA.html for a historical perspective.) From the existing perspective, however, forests have the advantage of being readily viewed in a watershed context. This is due in large part to the scale of operations and management of a forest system. The primary environmental indicators of success or failure are stream water quality and associated aquatic habitat. This has led to an emphasis on riparian zones and buffer strips to retain sediment and nutrients. Such an approach automatically integrates land area responses, but it is complicated by multiple users and stakeholders.

Multiple Use Conflicts

When water resources are managed to achieve a specific purpose, such management is likely to preclude, or at least interfere with, alternative uses. Irrigation, drainage, and erosion control are examples of water management practices that support sustainable agriculture. However, irrigation may exhaust water resources desired for urban or industrial uses or reduce water quality and thus adversely affect fish and wildlife. Similarly, drainage may remove wetlands and eliminate nesting areas for migrating birds. Thus, major conflicts can arise. Whereas soil and hydrologic sciences can often explain or even predict the consequences of specific actions, resolving the conflicts generally requires input from the social sciences.

Many countries, states, and regions are adjusting their soil water practices to account for diversity in the opinions of stakeholders. Some of the policy direction is implicitly or explicitly directed by a watershed approach, simply because one cannot neglect interactions between land areas related to geomorphic and hydrologic factors. Development of appropriate strategies and specific practices is a site-specific endeavor that will lead to balanced resource use,

not only to protect the environment but also to satisfy the people depending on the resource. Policy decisions will vary by region according to political circumstances, social desires, and economics as well as the physical and biological situation. To be effective, nature demands that an integrated watershed approach be used.

EXAMPLES OF HISTORICAL PRACTICES

There are many examples of soil and water management practices from around the world that could illustrate the importance of a watershed approach. If space permitted, one could explore case studies on drainage of the Nile River Delta in Egypt, soil erosion of the Loess Plateau in China, historical land clearing and intensive agriculture throughout Europe, salinity and phosphorus issues in landscapes across Australia—including the Murray–Darling river basin and the wheat belt of Western Australia—and a variety of problems requiring (in hindsight, at least) an integrated watershed management approach. This entry limited to three important concepts briefly illustrated by the following case studies.

Colorado River, United States

The Colorado River Basin includes parts of seven U.S. states as well as a part of Mexico. The river rises as a pristine series of streams in the high Rocky Mountains and eventually drains into the Gulf of California. The average annual flow of the river is about $1.7 \times 10^{10} \text{ m}^3$. Based on a relatively wet period of record, however, the courts have decreed that the seven U.S. states are entitled to $1.8 \times 10^{10} \text{ m}^3$, and by treaty it has been agreed that Mexico is entitled to $1.8 \times 10^9 \text{ m}^3$. Furthermore, water quality standards have been imposed in terms of salinity (total dissolved solids). The origin of the salts is dissolution of minerals from the geologic formations and soils through which the water flows. The concentration of salts is increased when irrigated crops transpire pure water and thus pass on all the salts in a smaller volume of return flow.

Colorado River water is used for irrigation, as a municipal supply in cities like Los Angeles, and for many other uses. When the river finally reaches Mexico, the flow is minimal and the salt concentration tends to be high. Clearly, the legal entitlements cannot be met with the water that nature provides. This water shortage and its distribution have been litigated for three-quarters of a century.

An example of an effort to reduce the problem somewhat is pertinent here. In the Grand Valley of Colorado, some 28 million hectares were irrigated with Colorado River water when the Colorado River Salinity Control Program was started in the late 1970s. It was considered the largest single source of salt to the Colorado River. To maintain the agriculture and at the same time protect the river, a large project was implemented to line delivery canals,

replace some of the ditches with pipe, and improve on-farm irrigation efficiency by the introduction of a number of modern practices. These local practices integrated over the Grand Valley had a significant impact on the quantity and quality of water contributing to the Colorado River. The U.S. Bureau of Reclamation provides additional information at dataweb.usbr.gov/html/grandvalley2.html.

San Joaquin Valley, California, United States

In the 1920s, plans were developed to transport substantial amounts of water from northern California to the San Joaquin Valley, primarily for irrigation. Although engineers warned that drainage needed to be provided to make the irrigation enterprise viable, political and financial obstacles prevented the building of a drainage facility for decades. When parts of the nearly 20 million hectares Westlands Irrigation District started to suffer substantially from waterlogging and salinity, one-half of a large drain (the upper half only!) was installed, with its water discharged “temporarily” into a low area euphemistically named the Kesterson Wildlife Refuge. Whereas the drain appeared to be successful as a salt-removal system, even if not completed, it soon became evident that selenium originating in the soils was transported into the Kesterson Reservoir at concentrations sufficient to greatly damage, or kill, aquatic life and birds landing on the water. Finding a solution acceptable to all parties has been difficult. The interests involved include naturalists, sports fishermen and hunters, and farmers. Space does not permit further exploration other than to note that similar adverse effects from trace elements leached from open soil systems have been discovered in other watersheds.

Kissimee River, Florida, United States

Humid regions also present challenges for soil and water management. One such environment in south Florida is a system of streams and wetlands flowing into Lake Okeechobee, just to the north of the well-known Everglades National Park. Florida is very flat, and in its natural state, the shallow Kissimee River meandered from the south end of Lake Kissimee to Lake Okeechobee through wetlands that absorbed and cycled nutrients from agricultural runoff. Occasional heavy rains caused the river to overflow its natural banks and flood adjacent lands.

In the 1960s, the U.S. Army Corps of Engineers was commissioned for half a million 1962 U.S. dollars to dredge a straight canal (called C-38) with water-control gates and boat locks. The dimensions of the river were changed from approximately 166 to 90 km long, from 30 to 91 m wide, and from 3 to 10 m deep. This provided for navigation and flood control but dramatically changed the water quality and ecology. As a result, large-mouth bass

and water fowl diminished in the Kissimee River ecosystem, and nutrients transported to Lake Okeechobee increased eutrophication problems.

In 1990, the State of Florida adopted the South Florida Water Management District's restoration plan (see www.sfwmd.gov for more details), and the U.S. Congress funded 50% of the estimated \$372 million cost through the 1992 Water Resources Development Act. The plan includes acquisition of approximately 360 km² of land, backfilling large portions of the canal, and attempting to return the Kissimee River to its natural state. Further details of this project can be found at fcn.state.fl.us/eog/govdocs/opbenv/saveglades/everglades/html/kissimee.htm.

What Lessons Have We Learned?

The discussion here gives the reader an overview of soil and water management as an integrated process using the watershed approach. While it is true that the watershed approach integrates several processes and landscape factors, it also involves disaggregation of the watershed into its various geographical parts. Both issues are challenging, primarily due to natural and human-induced variability and uncertainty in space and time. However, the advent of readily available spatial data is making research on these topics feasible, and in time sound management practices should follow.

The watershed approach to soil and water management also addresses political and economic issues of the

stakeholders involved in regional, national, and international policy and decision making. Downstream water users have long recognized the importance of upstream land use practices, and it seems policy makers are increasingly facing the challenges of integrated watershed management for water quantity and quality. As history shows, practices of soil and water management are based primarily on social concerns and politics with varying degrees of import being placed on scientific understanding and engineering considerations. Regardless of the technical and political reasoning, some compromises or trade-offs will be required.

Watershed Management: Remote Sensing and GIS Applications

A.V. Shanwal

Department of Soil Science, Chaudhary Charan Singh Haryana Agricultural University, Hisar, India

S.P. Singh

National Bureau of Soil Survey and Land Use Planning, Indian Council of Agricultural Research (ICAR), New Delhi, India

Abstract

Remote sensing (RS) and geographic information system (GIS) are important technologies for addressing challenges in sustainable management of natural resources. Remotely sensed data (e.g., aerial photographs and satellite imagery) can be used to obtain information on soils, land use, vegetation, slope gradient, runoff, erosion, etc. However, developments in a multispectral scanner, radar system, and a multitude of quantitative techniques for analyzing and processing such data provide opportunities for data acquisition through RS and an array of techniques for data analyses.

INTRODUCTION

The need for natural resources conservation must be considered in any agricultural development plans involving conversion of new land use to increase production. An action plan to minimize natural resources degradation must be based on the principles of sustainability so that soil can be handed over to the next generation under better conditions than received from the previous generation. Thus, management practices must be ecologically sound, economically feasible, and socially and politically acceptable.

Natural resources degradation can be contained by adopting the watershed as a hydrological unit for development and management. This approach is multidisciplinary, broad based, and intensive vis-à-vis the simple “Seed and Fertilizer Approach.” Despite the investment, it is an economic approach in the long run.^[1]

The degradation of improperly used watersheds happens because of an increase in soil erosion, decline in soil productivity, reduction in livestock-carrying capacity, decline in forest cover and perturbation in ecological equilibrium, and reduction in biodiversity. The problem requires a high-tech solution with back-up policy decisions.

Geographic information system (GIS) is an important tool for tracking spatial data. GIS draws the composite map by superimposing the data and image files obtained from traditional methods and satellite imageries; allows us to develop, analyze, and display spatially explicit information; and gives us the ability to deal with the larger spatial scales in process such as soil erosion and drainage (≤ 500 acres) and regional landscape (several million acres).

INVENTORYING AND MONITORING

Despite efforts at inventorying and monitoring, conventional techniques provide only sketchy information on resources in a watershed, their location, and spatial and dynamic distribution. Of inventorying and monitoring, the latter is probably the major new thrust for resource managers and scientists.

Improved management practices are not thought of spontaneously prior to testing and implementation. Such practices have evolved over time through experimentation, experience, and trial and error. A case in point is the Bunga watershed in Amabala, Haryana, India.^[2] As was expected, numerous components did not work properly. Neither the rate of runoff nor the outflow from the reservoir was in harmony in the initial stage. High rate of siltation of Sukhana Lake near Chandigarh, Haryana, India, due to severe soil erosion in the catchment area is another example of a dire need for inventorying of data prior to starting any project.^[3] Because of high siltation, the ponded area of Sukhana Lake decreased by about 30 ha between 1980 and 2000. During this period, the courses of Sukhana and Kansal streams feeding the lake also changed considerably. The siltation of Sukhana Lake is the result of poor vegetation cover and heavy runoff in the catchment within the Shiwalik Hills.^[3]

It is thus important that remote sensing (RS) and GIS specialist and the resource managers must work together to determine the specific information needed (e.g., the nature of earth surface cover and their characteristics; the location, size, terrain, and other characteristics of the watershed area involved). Relevant information needed includes the format

(e.g., maps, tables, and scales); time frame for both collecting and processing the data; level of accuracy and reliability; and costs of obtaining and interpreting/processing the data.

RESEARCH AND DEVELOPMENT

Using watershed, landscape or ecosystem approaches have broad support as a means in achieving sustainable use of natural resources and integrating objectives on a practical scale. Addressing watershed management issues on large scales requires enhanced technical capabilities and modern set of tools and facilities.

Landsat-1 was launched in 1972 and the Landsat thematic mapper (TM) type of data has been in existence only since 1984. Thus, a tremendous amount of progress has been made over a short time in developing effective methods of processing and analyzing such data. The last decade of the 20th century witnessed rapid advances and significant increase in the operational use of remotely sensed data.^[4]

Landsat-7 launched in 1998 carries enhanced thematic mappers and pointable sensor with improved spatial

resolution and signal-to-noise ratio (Table 1). The Earth Observing System consists of a morning (AM) and an afternoon (PM) components and carries five separate sensors including MODIS, a 36-narrow band imager with 1-km spatial resolution.^[6] These sensors are significantly improved in their capability to map watershed information classes. These advanced sensors and computational capability have new requirements for satellite data processing algorithms. Added to the image analysis system, there is also a need for RS algorithms for estimating biophysical parameters necessary to drive and validate the watershed process models.^[5]

During the 1980s, advances in computer hardware, particularly speed and data storage, catalyzed the development of software for handling spatial data. One of the most significant products of this period of rapid technological change was the development of GIS (Table 2). It has made a tremendous impact in identifying strategies of watershed development by manipulating and analyzing individual “layers” of spatial data and providing tools for analyzing and modeling the interrelationship among layers. The GIS also provides a means of displaying complex watershed information in a comprehensible manner.

Table 1 RS satellites with advanced sensors.

Satellite	Country	Sensor		
		Name	Spectrum	IFOV
Landsat-7	U.S.A.	ETM ⁺	0.45 ~ 12.50 μm (8 bands)	30 m
SPOT-4	France	HRVIR	0.50 ~ 1.75 μm (5 bands)	10 m
IRS-1D	India	PAN	0.50 ~ 0.75	5.8 m
		LISS-III	0.45 ~ 0.86 1.55 ~ 1.70 (5 bands)	24.0 m
RADARSAT	Canada	WIFS	0.67 ~ 0.86	188 m
		SAR	5.3 GHz	25 × 28 m
TRMN	Japan	VIRS	0.63 ~ 10.7 (5 bands)	2 km
		TMI	10.65 ~ 85.5 GHz	5.6 km × 3.8 km
		CERES	0.3 ~ 50 μm (3 bands)	25 km
		LIS	0.7774 μm	5 km
NOAA-M	U.S.A.	AVHRR/3	0.58 ~ 12.40 μm (6 bands)	0.5 km
CRSS	U.S.A.	PAN	0.45 ~ 0.90 μm	0.82 m
		MSS	0.45 ~ 0.90 μm (4 bands)	3.20 m
ADEOS	Japan	OCTS	0.402 ~ 12.5 μm (12 bands)	700 m
		AVNIR	0.40 ~ 0.92 μm (5 bands)	8 m
EOS-AM	U.S.A.	ASTER	0.52 ~ 11.3 μm (3 bands)	15 m
EOS-PM	U.S.A.	MODIS-N	0.659 ~ 14.24 μm (5 bands)	250 m
EOSAT	U.S.A.	PAN	0.45 ~ 0.90 μm	1 m
		MS	0.45 ~ 0.90 μm (4 bands)	4 m

Note: ETM, enhanced thematic mapper; HRVIR, high resolution visible and middle infrared; LISS, linear imaging self-scanner system; SAR, synthetic aperture radar; VIRS, visible infrared scanner; TMI, TRMM microwave imager; CERES, clouds earth's radiation energy system; AVHRR, advanced very high resolution radiometer; OCTS, ocean color and temperature scanner; AVNIR, advanced visible and near infrared radiometer; ASTER, advanced space borne thermal emission and reflectance radiometer; MODIS, moderate resolution imaging spectrometer-nadir; PAN, panchromatic; MS, multispectral; IFOV, instantaneous field of view.

The GIS also provides a means of predicting the outcomes of alternative courses of action, from both spatial and temporal perspective and in a timely and cost-effective manner. However, it does not preclude the need for monitoring the ground truth as a guide to development of management practices.

The last decade of the 20th century witnessed rapid advances and a significant increase in the operational use of RS and GIS in watershed management.^[9] Much of this increase in operational use is due to the continued integration of RS, GIS, global positioning system (GPS), and crop model (CM) techniques.^[10] These four technologies form a powerful, interrelated combination (Fig. 1). In watershed management, there has been a continuous increase in the use of RS data to provide input to new GIS database, upgrade existing database, and monitor land use changes.

In addition to providing input to GIS database, the RS data enable significant improvements in classification accuracies. Further, GPS capabilities provide effective cartographic control to the GIS database and will enable field plots to be located efficiently and accurately in the data set.

The integration of GIS and CMs has proven very successful for alternative land use planning in the watershed.

**Fig. 1** Relationship between RS, GIS, GPS, and CM.

The important ones are Decision Support System for Agro-technology Transfer, Agricultural and Environmental Information System for Windows, Intelligent Decision Support System, and Decision Support System Engine. These simulation models are capable of predicting the potential yields of crops (rice, cassava, potato, sugarcane, sunflower, maize, wheat, barley, millet, sorghum, soybean, peanut, drybeans, tomato, and chickpea) in different physiographic units of a particular watershed. In addition, several GIS-based simulation models have been developed for natural resources management and are used in watershed management.^[11] The important ones are Scheduling and Network Analysis Program, Land Use Analysis System, and LANDSIM and Land Information System. All these models involve database (non-spatial), GIS, model base (simulation analysis), and a graphic user interface.

CHALLENGES AND OPPORTUNITIES AHEAD

Rapid advances in RS and GIS technologies can bring about quantum leap in watershed management. The challenge lies in assuring that RS and GIS technologies continue to serve the practitioners and users, but not vice versa.

However, GIS and RS are both a panacea and a Pandora's box. These are panacea because of the promise to meet the challenges of resource inventory and monitoring, and planning and policy analysis. These are Pandora's box because of the numerous pitfalls of using the tools wrongly, capturing the data poorly, miscommunicating information, conveying incorrect results, and overselling the capabilities.

The dilemma can be addressed by a careful integration of RS, GIS, and other simulation models in watershed management and with due consideration of the following:

1. Designing the classification system as totally exhaustive, mutually exclusive, and hierarchical.
2. Determining the temporal and spatial scale of the watershed by accommodating GIS and RS at multiple

scales without compromising flexibility and quality of a project.

3. Identifying the appropriate data sources (such as video, aerial photography, satellite imagery, and airborne scanner) for different land cover.
4. Assessing and reporting the accuracy of the data needs.
5. Limiting the scope of the project according to the budget and schedule.
6. Standardizing the formats needed for the exchange of information across projects and eliminating duplication.

Further changes may include the following:

1. Developing effective techniques of integration and analysis of data from various sources such as advanced very high resolution radiometer and Landsat TM or SPOT data or Landsat TM plus satellite radar data.
2. Converting research into operational applications in watershed management.
3. Developing effective expert system to assist the analyst.
4. Educating and training the user community in principles and theory of these technologies so that they can use these powerful tools wisely, appropriately, and effectively.

Anticipated developments and opportunities in these technologies comprise the following:

1. Economic availability of satellite optical sensor data with improved spatial, spectral, radiometric, and temporal resolutions.
2. Availability of operational multifrequency, multipolarization synthetic aperture radar data from satellite altitudes.
3. Improvement in computer storage and processing capabilities.
4. Better understanding and use of combined data from optical, microwave, and other remote sensors.
5. Integration of RS, GIS, GPS, and CM technologies.
6. Increased use of expert systems for data analysis.

These developments will improve the quality and characteristics of the data and analytical capabilities in the area of watershed management. A combination of knowledgeable resource managers and practical farmers with the technological tools and data available to them holds great promise for identifying effective watershed management technologies.

CONCLUSION

A variety of information about the characteristics and condition of the area is needed for judicious management of watershed. Aerial photography has been used since the 1950s for obtaining information on soils, land use, vegetation, slope, runoff, erosion, etc. The advent of space

research through satellite, multispectral scanner, and radar data, and quantitative analytical techniques of processing such data has increased the array of data, analysis procedure, and results that can be obtained using RS capabilities.

During the 1980s, advances in computer hardware for processing and data storage catalyzed the development of software for handling spatial and image digital data. These technologies played an important role in the development of GIS for natural resource management, especially in preparing composite map superimposing the data and image files.

During the 1990s, significant development in GIS technology and integration of RS, GIS, GPS, and crop simulation model techniques have created additional complexity and opportunities of using various data sources and analysis techniques for obtaining the information needed by the resource managers. There are some critical issues that need to be addressed for integration of RS, GIS, and other technologies to obtain information needed for sustainable natural resource management through watershed development.

Weathering

Dominique Righi

Hydrology, Clay, Soils and Alterations, National Center for Scientific Research (CNRS), Poitiers, France

Abstract

Clay minerals are the principal products of weathering and soil formation, which are essentially water–rock interaction processes. Clay formation occurring at the earth's surface is a slow reaction process, meaning that some initial materials are only partially reacted and are not in equilibrium with the medium in which they are located. This creates the potential for further transformation of altered products. If the chemistry of the ambient soil or surface materials is changed, e.g., by pollution containing chemicals, there will be a high potential for change in the clay mineralogy of the surface material. Thus, the type of clay minerals produced by weathering reactions and their rate of formation are of the greatest importance in environmental problems.

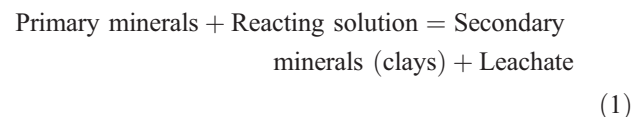

INTRODUCTION

Weathering is the alteration of materials at, or near, the earth's surface in response to the conditions that prevail there.^[1] It results from a complex set of interactions among the lithosphere, atmosphere, hydrosphere, and biosphere. The minerals that constitute the lithosphere are conventionally divided into primary and secondary phases (Fig. 1). *Primary* phase minerals, produced at depth by high-temperature and/or high-pressure processes, are found in igneous and metamorphic rocks. *Secondary* phase minerals are transformations (secondary minerals that result from partial breakdown and reorganization of the primary phase minerals) or neoformations (secondary minerals that precipitate directly from solutions in contact with the rock) produced at the expense of primary phase minerals as a result of weathering. In most earth-surface systems, secondary phase minerals include various clay minerals (e.g., aluminosilicates), oxides, and hydroxides. The aqueous phase (hydrosphere) enters the weathering system as atmospheric precipitations, whose chemistry and abundance are determined by climatic and other atmospheric factors. Within the weathering system, the aqueous phase is rapidly modified by the interaction with solids, including biomass. The dissolution of the most soluble minerals in the system (weathering phases) and precipitation of the least soluble minerals (new phases) tend to control the chemical composition of the aqueous phase. Residence time of the water in the weathering system is another important factor, so that a complex set of interactions connects the aqueous phase with other weathering factors.

Biomass is a major influence on the chemistry and behavior of water in weathering systems.^[2] The major effect of organic compounds is concentrated in the upper meter of the soil. Biomass yields important organic products containing

chemical functional groups, such as carboxyl and phenol, that provide protons to the weathering system. Many of these products can attack a mineral surface directly to release ions into solution. Moreover, complex organic acids, such as oxalic and citric acids, are efficient in mineral breakdown because they hold cations (e.g., Al^{3+} and Fe^{3+}) in solution that would otherwise precipitate.

Weathering is a form of reaction that may be written schematically^[3] as follows:

This process is strongly influenced by the chemical composition of the rock (i.e., the nature of its primary minerals) and environmental factors (e.g., climate, living organisms, and hydrodynamics). The environmental factors act through the aqueous phase, which is the first requirement of weathering.

MAIN WEATHERING MECHANISMS

Weathering mechanisms are determined by the highly variable physicochemical characteristics of the reacting solutions. Therefore, it is helpful to classify them as a function of the ionic concentration and the pH of these solutions.^[2,3]

Acidolysis and Acidocomplexolysis

The low pH of <5 of this weathering alteration is obtained through the dissociation of organic acids. However, the effect on the mineral fraction is determined by the type of

Fig. 1 Photograph from a thin section of a weathered rock (amphibolite) showing remnants of primary mineral (P) which is amphibole. Indicated by (S) are the secondary minerals (clay minerals) produced by reaction between the primary mineral and fluid percolating through the network of pores and fissures. Bar is 50 μm .

acid involved. Acidolysis, caused by non-complexing organic acids, acts similarly to hydrolysis (see below), whereas acidocomplexolysis, which involves strongly complexing acids (e.g., oxalic and citric), leads to the destruction of all minerals except quartz and others that are highly resistant. Aluminum (Al) and iron (Fe) are solubilized as metalorganic complexes. Acidocomplexolysis is typical for the pedogenetic process called podzolization, in which organic acidity and complexing ability are the important factors.

Hydrolysis

In this alteration, weathering is by pure water or water with dissolved carbon dioxide, which induces a pH of 4.5–6. Hydrolysis may be complete or only partial. Complete hydrolysis leads to the formation of Al hydroxide (gibbsite) and Fe oxides and oxyhydroxides (hematite and goethite), whereas partial hydrolysis leads to the formation of kaolinite or smectite clays as secondary minerals.

Salinolysis

Solutions in this weathering alteration are slightly alkaline and have a high ionic strength. This type of alteration is common in semiarid climatic zones, where there is a strong tendency for the aqueous phase to evaporate. The result is the precipitation of evaporite minerals (sulfates and chlorides) and the formation of various smectite clays.

Alkalinolysis

The aqueous solution in this alteration is salty and strongly alkaline, with a pH of 9 or more. As with salinolysis, evaporitic minerals form, but Al and silicon (Si) may reach relatively high concentrations in solution. This allows the formation of sodium smectites and alkaline zeolites.

Secondary minerals produced through salinolysis and alkalinolysis mechanisms are essentially by precipitation from solution processes (neoformation). However, the required high Si and magnesium (Mg) concentrations in the soil solution are most often reached by the alteration of pre-existing silicate minerals. For example, the dissolution of quartz at a high pH ensures that substantial soluble Si is available for the neoformation of secondary phyllosilicate phases.

BASIC STRUCTURE OF A WEATHERING PROFILE

Over time, weathering processes lead to the development of a weathering profile.^[4] The basic structure of the weathering profile of a basement rock shows successive zones or horizons (Fig. 2). In the crystalline rock, which is considered the basic starting unit of this rock, all the minerals become unstable within the earth's surface conditions and are replaced by clays (secondary minerals), and ions are lost to the percolating aqueous solution.

Rock

The zone in which water–rock interactions begin is the initial unaltered rock. All rocks contain many cracks and fissures caused by the release of thermal and pressure constraints produced at depth. These cracks and fissures are the initial paths of penetration of the altering fluid. In the first stages of weathering, zones near cracks show intense alteration, whereas the zones furthest from the cracks remain unaltered. In the upper horizon of the bedrock, initial formation of clay minerals is localized around the initial cracks in the rock. Thus, in the initial stages of weathering, a rock sample is heterogeneously altered.

Saprock

The first zone of generalized alteration is called saprock. In this zone, the minerals are partially or totally transformed into clays (secondary minerals), but the petrographic structure of the rock (i.e., the location and size of the initial mineral grains) is largely maintained. The overall quantity of clays is greatly increased over that of the basement rock through the alteration and transformation of the original minerals. The most important feature of this zone is the

Fig. 2 Schematic representation of a weathering profile showing the successive zones or horizons.

Source: From Righi & Meunier.^[4]

extreme heterogeneity of the mineralogy, with many types of clays and large portions of unaltered or little-altered rock minerals.

Saprolite

The next zone is that of saprolite, where there is little or no rock structure left and clays predominate. The effect of chemical transformation is the greatest here; most of the original minerals are greatly altered. Due to a high degree of mineral transformation in the upper part of the saprolite

zone, the rock structure often collapses, and the initial fractures and fissures are lost.

Organo-Mineral Soil

The uppermost weathering zone commonly contains the soil. This is where, in a natural and undisturbed state, the biogeochemical processes become predominant. The chemical and physical properties of the system are dominated by pore structure. This is a secondary structure due to the weathering transformations which have totally effaced any rock structure. When porosity is sufficiently advanced to allow the establishment of organisms, their secretions and breakdown products induce a more rigorous weathering and the formation of soil type characteristics of the prevailing environmental conditions and vegetation.

BASIC FACTORS IN WEATHERING

Weathering is the result of a complex set of processes, which is controlled by a set of interacting factors. Soil-forming factors, including rock material, climate, vegetation, topography, and time, are relevant for weathering.^[5] In some cases, human activity disturbs natural soils so much that it could be considered an additional factor of soil formation.

Four variables govern weathering processes.^[6] The first is *rock type*, which is a chemical factor. The second, *climate*, is composed of rainfall (a chemical factor) and temperature (a physical factor). The third, *flow rate*, is a chemical factor because it determines, through drainage, the ratio of aqueous phase to rock and its contact time with rock. The fourth variable is the *age* of a weathering sequence, which is a physical parameter (time). The chemical factors of rock composition and flow rate are probably the most important in determining the type of secondary minerals (clay minerals) that will be produced.

On the *continental scale*, flow rate is determined by climate. In free-flowing water systems, drainage can be considered the driving force of weathering. Removing the leachate creates a mass action effect favoring the breakdown of the primary phase minerals. In humid zones, where drainage is free, such subtractive weathering processes lead to the accumulation of Si, Al, and Fe, and the elimination of all other major cations. Kaolinite (an Al-rich clay mineral), gibbsite (Al hydroxide), and goethite and hematite (Fe oxyhydroxide and oxide) are the secondary minerals that form. Thick weathering profiles (20 m or more) characterized by this simple clay mineral assemblage, often called laterite,^[7] cover much of the intertropical zone. Under drier conditions, the aqueous phase may develop high ionic concentrations, leading to the precipitation of salts and/or formation of smectite or fibrous clays.

On the *watershed scale*, flow rate is determined by slope gradient. Similar to the effect of climate, the slope controls

the water residence time and, hence, the chemistry of the reactions. The greater the slope, the more rapid the displacement of the aqueous solutions over the weathering zone. Moreover, material leached out of the upper part of the slope may deposit in the lower part. Therefore, the general type of secondary minerals changes with the slope. In the upper areas where water residence time is short, oxides of Fe and Al tend to form. As one proceeds down-slope, kaolinite is more abundant and, in the lower regions, minerals such as smectites form.

On the *rock fragment* or *mineral scale*, porosity induces similar effects. In the larger pores of the system (1 mm or more in diameter), where time of contact between minerals and aqueous phase is short, kaolinite or Al and Fe oxides may form. In smaller pores (<1 μm diameter), longer residence time for the aqueous phase leads to higher concentrations of cations, which explains why smectites form at grain boundaries in solid rocks. In these systems of low water–rock ratio and long contact time, the chemical composition of the rock or mineral is very important in determining the secondary minerals (type of clay minerals) that will form. Acid rocks having a large proportion of potassium feldspar and quartz will produce kaolinite, aluminous smectite, or illite (mica-like) clays. On the other hand, basic and ultrabasic rocks, which contain a large proportion of ferromagnesian minerals, will produce saponite, vermiculite, and chlorites (Mg- and/or Fe-rich clays) as weathering products. The parent rock effect is greater during the early stages of weathering or pedogenetic evolution. As weathering progresses (time increases), chemical leaching removes all but the most refractory components.

CONCLUSION

Clay minerals are the principal products of weathering and soil formation, which are essentially water–rock interaction

processes. Clay formation occurring at the earth's surface is a *slow reaction process*, meaning that some initial materials are only partially reacted and are not in equilibrium with the medium in which they are located. This creates the potential for further transformation of altered products. If the chemistry of the ambient soil or surface materials is changed, e.g., by pollution containing chemicals, there will be a high potential for change in the clay mineralogy of the surface material. Thus, the type of clay minerals produced by weathering reactions and their rate of formation are of the greatest importance in environmental problems.

Abstract

The chemical weathering of geologic materials by carbonic acid, including both aluminosilicate and carbonate minerals, converts carbon dioxide (CO₂) to bicarbonate/carbonate ions that are later precipitated as carbonate minerals in soils and sediments, thus removing and sequestering CO₂ from the atmosphere. Over periods of geological time, this process is a major control on the partial pressure of CO₂ in the atmosphere. Chemical weathering rates, and hence CO₂ consumption, are influenced by a variety of geological, climatological, and biological factors, such as temperature, precipitation, vegetation cover, bedrock type, depth of the regolith, and tectonic activity. Further work has demonstrated a significant relationship between chemical and physical weathering and a tight coupling between tectonic processes and chemical weathering. In addition to the direct consumption of CO₂ by the weathering reaction, the chemical weathering is the major process releasing soluble nutrient elements such as potassium, calcium, and phosphorus (P) to ecosystems. The production of these nutrients helps promote biomass growth and development, which in turn sequesters CO₂ by photosynthesis. Because rates of weathering and therefore rates of base cations and P production in soils are influenced by both climatic and tectonic regimes, an important linkage between geological processes and ecosystem development exists.

INTRODUCTION

Chemical weathering is the chemical alteration of minerals into new minerals and/or dissolved ions. The reaction involves water and/or an acid. Although various anthropogenic activities, including fossil-fuel burning, have introduced compounds such as NO_x and sulfur dioxide into the atmosphere and these components can react with water to form strong acids, namely nitric acid and sulfuric acid (i.e., “acid rain”), the primary acid consumed in the chemical weathering of both carbonate and aluminosilicate minerals is carbonic acid (H₂CO₃). Upon the dissociation of H₂CO₃, the hydrogen ions produced to attack the minerals present in soil, and chemical weathering occurs. If carbonate minerals such as calcium carbonate (CaCO₃) are present, congruent weathering takes place and the entire mineral is dissolved (CaCO₃ + H₂CO₃ → Ca²⁺ + 2HCO₃⁻). Most aluminosilicate minerals weather incongruently, such that both soluble ions and an insoluble weathering product, a clay mineral, are produced

(2KAlSi₃O₈ + 9H₂O + 2H₂CO₃ → 2K⁺ + 2HCO₃⁻ + 4H₄SiO₄ + Al₂Si₂O₅(OH)₄). In this reaction, 2 moles of potassium ion (K⁺) and bicarbonate are produced along with 4 moles of silicic acid (dissolved Si) for every 2 moles of K feldspar consumed. In addition, 1 mole of insoluble kaolinite clay is left behind in the soil.

Because the carbon dioxide (CO₂) in H₂CO₃ originates from the atmosphere (either directly from the atmosphere or indirectly from the root respiration or decomposition of plant materials), the consumption of CO₂ via chemical weathering is recognized to be a major control or “sink” for CO₂ over time and hence an important driver of climate change. In terrestrial systems, two major processes sequester atmospheric CO₂ as follows: the photosynthetic production of organic carbon (C) and its subsequent burial and the chemical weathering.^[1] Over long periods of geological time, the chemical weathering of aluminosilicate minerals is a primary control of CO₂, while on shorter timescales (few thousand years), the weathering of carbonate minerals also

serves as a “sink” for CO_2 .^[2] The CO_2 consumption rate via weathering is $\sim 2.4 \times 10^{13} \text{ mol C yr}^{-1}$.^[3] Of this, 51% is from carbonate mineral weathering. Empirical data from both available studies and the geological past indicate that chemical weathering rates are indeed directly proportional to the amount of CO_2 present in the system.^[4,5] See also the entry *Clay Minerals: Weathering and Alteration of*, p. 430.

WEATHERING RATES AND CO_2 CONSUMPTION

All the minerals do not weather at the same rate. Minerals formed under conditions furthest removed from earth surface conditions [i.e., high tritium and phosphorus (P)] weather the fastest. Therefore, the processes that formed these minerals and their chemical composition have important influences in the rate of chemical weathering at any given location. Olivine group minerals $[(\text{Mg,Fe})\text{SiO}_4]$, which are found in many volcanic rocks, are among the least stable at surface conditions, while quartz found, e.g., in sandstones is one of the most stable and most resistant to weathering.^[4] In general, continental igneous rocks with more felsic minerals weather at about half the rate of volcanic rocks with mafic minerals.^[6] In the earth's history, the chemical weathering of volcanic rocks could have accounted for more than 80% of the total chemical weathering of the continents.^[1] Because of this, volcanic rocks are an important component to overall global aluminosilicate weathering and the consumption of CO_2 .^[6]

Lasaga^[7] compared the dissolution rates of several silicate minerals at 25°C and pH 5 and was able to calculate the time required for complete dissolution of crystals 10^{-3} m in size. The result for forsterite (Mg_2SiO_4), an olivine group mineral, was 600,000 years compared with 2.7 million years of muscovite and 34 million years of quartz. Appreciable differences often exist when rates of mineral weathering obtained from laboratory experiments are compared with rates estimated from field data. Discrepancies are to be expected given that many factors help control the rate of weathering, and hence CO_2 consumption. These include climate and hydrology, depth of the weathering profile, abundance of vascular plants, and whether the landscape is geologically active.

The last of those processes is referred to in geological nomenclature as tectonics. Tectonics implies, in part, the uplift of geological material and occurs primarily at convergent crustal plate boundaries. The uplift of crust to form mountains leads to increased erosion rates as relief is increased (and in many cases, increased orogenic precipitation occurs), so that a dynamic balance is reached between these two processes when a stable topography is achieved.^[8] Thus, chemical and physical weathering rates are closely coupled.^[9] Modeling indicates that the chemical weathering in continental crustal lithologies such as granite can range over more than an order of magnitude from tectonically

active regions to those that are geologically stable.^[8] These regions of high uplift rates include high-standing islands in the Western Pacific Ocean such as New Zealand and Taiwan that have very high CO_2 consumption rates per unit area via chemical weathering.^[9] This linkage between physical erosion and chemical weathering suggests that regions where rapid erosion occurs can be important regions of CO_2 consumption through the weathering process. Numerous authors have demonstrated the importance of vascular plants in enhancing chemical weathering as well as their overall role in C dynamics.^[10]

In addition to CO_2 sequestration through direct consumption by the weathering process, the chemical weathering provides soluble nutrients such as K, calcium (Ca), and P in soils that promote and enhance plant growth. This solubilization of nutrients by chemical weathering indirectly aids in C sequestration by aiding in the increase of ecosystem biomass through natural fertilization.^[8] In this regard, the production of nutrient elements is especially rapid in the regions of active tectonic uplift or new crustal production such as volcanism.^[11,12] In these tectonically active areas, fresh minerals are continuously supplied at a rapid rate, thereby exerting important influence in ecosystem development.^[12] In forested ecosystems in Taiwan, only ~9% of the P solubilized by chemical weathering is lost via stream discharge, as the rest is retained within the ecosystem.^[12] On the other hand, the atmosphere is the major source of fixed nitrogen (N) to the landscape. The N/P ratio of the inputs to the Taiwanese forests is 6:1, thus maintaining the ecosystem in a probable state of N deficiency, as predicted by the model of Vitousek.^[11] In areas where there is little tectonic activity, P and other essential nutrients like base cations can be rapidly (a few thousand years) weathered from rocks and soils, leaving them deficient in these important components.

WEATHERING OF CARBONATE MINERALS

CaCO_3 dissolves congruently upon reaction with H_2CO_3 . Although this reaction initially consumes CO_2 , after transfer to the oceans, CaCO_3 is eventually formed and CO_2 is produced via the back reaction. Thus, on geological timescales, carbonate mineral weathering has not been considered an ultimate sink for CO_2 .^[13] The widespread addition of lime to agricultural soils has led to significant carbonate mineral dissolution on agricultural lands, and hence enhanced CO_2 sequestration and HCO_3^- input to the oceans.^[14]

CHEMICAL WEATHERING AND CO_2 OVER GEOLOGICAL TIME

Modeling calculations, based in part on chemical weathering constraints, indicate that the CO_2 concentration of the earth's atmosphere has varied greatly over the past 540 million years. Values as high as 15 to 20 times

compared with pre-anthropogenic times occurred ~520 million years ago, and existing values compared with pre-anthropogenic times occurred between ~350 million years and 260 million years ago.^[6] These modeling exercises suggest that a CO₂ threshold below ~500 ppm is needed for the initiation of widespread glacial conditions and that a tight relationship between global temperature and atmospheric CO₂ concentration existed throughout the last 540 million years of earth's history.^[1]

SOIL CARBONATES

Meteoric water falling on exposed land is the primary agent of weathering reactions. Baumgartner and Reichel^[15] reported that the average annual rainfall on exposed lands is 74.6 cm yr⁻¹ but noted that only 36% (26.6 cm yr⁻¹) actually percolates through the soil to the groundwater. Thus, huge variations in "effective" percolation occur as a function of climate and relief. In dry regions, atmospheric CO₂ may be sequestered through the formation of pedogenic carbonates, especially when Ca is derived by the weathering of aluminosilicate minerals. Pedogenic carbonates occur in different morphological forms as needles, laminated layers, or precipitates in interstitial spaces and as coatings on the underside of stones. They also occur as threads, concretions (glebules), and pendants below peds and around roots.^[16] There are four principal mechanisms for the formation of pedogenic carbonates:^[17]

1. The per descendum model: carbonates are precipitated in the subsoil following dissolution of preexisting carbonates or aluminosilicates in the upper soil layers followed by the vertical translocation of soluble elements to the subsoil with the local wetting front.
2. The per ascendum model: the capillary rise of Ca-carrying water from a shallow water table leads to the deposition of pedogenic carbonates in the upper soil layers.
3. The *in situ* model: there are *in situ* dissolution and reprecipitation of carbonates in proximity to the parent material or bedrock.
4. The biogenic model: secondary carbonates are formed aided by biological factors (e.g., termites, microbes, and plant roots).

The rate of formation of carbonates in some soils of the United States and Canada ranges from 1.5 to 21.5 kg C ha⁻¹ yr⁻¹ (Table 1). Ryskov et al.^[18] estimated that Chernozems and chestnut soils of Transbaikalia, Russia, bound 40–70 and 32 kg C ha⁻¹ yr⁻¹, respectively. Chen^[19] reported that in Australia, 0.5–1.0 m deep gypcrete horizons may form in 35,000–100,000 years. While the rates of formation of pedogenic carbonates are low at a decadal scale in comparison with those of sequestration by organic C as humus (100–1500 kg C ha⁻¹ yr⁻¹), the formation of

Table 1 Rate of C sequestration as pedogenic carbonates in North America.

Location	C sequestration rate (kg C ha ⁻¹ yr ⁻¹)
Mormon Mesa, Nevada	2.6–16.3
Whipple, California	1.5

Wetlands

Ralph W. Tiner

U.S. Fish and Wildlife Service (FWS), Hadley, Massachusetts, U.S.A.

Abstract

Wetland is a universal term used to describe the collection of flooded or saturated environments that have been referred to as marshes, swamps, bogs, fens, salinas, pocosins, mangroves, wet meadows, sumplands, salt flats, varzea forests, igapo forests, bottomlands, sedgeland, moors, mires, potholes, sloughs, mangals, palm oases, playas, muskegs, and other regional and local names. It has been defined as a basis for inventorying these natural resources, for conducting scientific studies, and, in some countries, for regulating uses of these areas. Given that wetlands include a diverse assemblage of ecosystems, classification schemes have been developed to separate and describe these different systems and to group similar habitats. Wetlands provide a number of functions that are considered valuable to society (e.g., surface water storage to minimize flood damages, sediment retention and nutrient transformation to improve water quality, shoreline stabilization, streamflow maintenance, and the provision of vital habitat for fish, shellfish, wildlife, and plants that yield food and fiber for people). Because of these values and the widespread recognition of wetlands as important natural resources, numerous wetland definitions and classification systems have been developed to inventory these resources around the globe. The purpose of this entry is to provide readers with an understanding of what wetlands are (wetland definition), how they vary globally (wetland types), and their extent as determined by various inventories. This entry should serve as a starting point for learning about wetlands, with the listed references being sources of more detailed information.

WETLAND DEFINITIONS

Wetlands are aquatic to semiaquatic ecosystems where permanent or periodic inundation or prolonged waterlogging creates conditions favoring the establishment of aquatic life. Wetlands are often located between land and water and have, therefore, been referred to as ecotones (i.e., transitional communities). However, many wetlands are not ecotones between land and water since they are not associated with a river, lake, estuary, or stream.^[1] Wetlands may derive water from many sources, including groundwater, river overflow, surface water runoff, precipitation, snowmelt, tides, melting permafrost, and seepage from impoundments or irrigation projects.

While the term “wetland” has many definitions, all definitions have common elements (see [Table 1](#); some definitions even include deepwater habitats). The presence of water in wetlands may be permanent or temporary. Their water may be salty or fresh. Wetlands may be natural habitats or artificially created. They range from shallow water environments to temporarily wet (i.e., flooded or saturated) areas. All are wet long enough and often enough to, at least, periodically support hydrophytic vegetation and other aquatic life (including anaerobic microbes), to create hydric soils or substrates, and to activate biogeochemical processes associated with wet environments.

WETLAND TYPES

Differences in climate, soils, vegetation, hydrology, water chemistry, nutrient availability, and other factors have led to the formation of a multitude of wetland types around the globe. In general, wetlands are characterized by their hydrology (e.g., tidal vs. non-tidal, inundation vs. soil saturation, and frequency and duration of wetness), the presence or absence of vegetation (vegetated vs. non-vegetated), the type of vegetation (forested or treed, shrub, emergent, or aquatic bed), and soil type (e.g., organic vs. inorganic and peatland vs. non-peatland). [Table 2](#) presents brief descriptions of some North American types, and [Fig. 1](#) shows examples of vegetated wetlands.

Various countries have devised classification systems for describing differences among their wetlands and for categorizing wetlands for natural resources inventories. Scientists have created systems to organize certain wetlands into meaningful groups for analysis and management (e.g., peatland classifications; see the study by Tiner^[1] for details). The Ramsar Convention Bureau^[2] published a multinational classification system to provide consistency for inventorying wetlands and designating wetlands of international importance. This system includes 11 types of marine or coastal wetlands (i.e., shallow water and intertidal habitats: permanent shallow marine waters; marine subtidal aquatic beds; coral reefs;

Table 1 Examples of wetland definitions used for inventories.

Country/organization	Wetland definition (source)
International/Ramsar	“areas of marsh, fen, peatland, or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish, or salt, including areas of marine water the depth of which at low tide does not exceed 6 m ... may incorporate riparian and coastal zone adjacent to wetlands, and islands or bodies of marine water deeper than 6 m at low tide lying within the wetlands.” ^[2]
Australia	“areas of seasonally, intermittently, or permanently waterlogged soils or inundated land, whether natural or artificial, fresh or saline, e.g., waterlogged soils, ponds, billabongs, lakes, swamps, tidal flats, estuaries, rivers, and their tributaries.” ^[3]
Canada	“land that is saturated with water long enough to promote wetland or aquatic processes as indicated by poorly drained soils, hydrophytic vegetation, and various kinds of biological activity which are adapted to a wet environment.” ^[4]
The United States	“lands transitional between terrestrial and aquatic systems where the water table is usually at or near the surface or the land is covered by shallow water.” Wetland attributes include hydrophytic vegetation, undrained hydric soil, or saturated or flooded substrates. ^[5]

rocky marine shores; sand; shingle or pebble shores; estuarine waters; intertidal mud, sand, or salt flats; intertidal marshes; intertidal forests; coastal brackish/saline lagoons; and coastal freshwater lagoons). This system also includes 19 inland wetland types (i.e., permanently flooded aquatic habitats to intermittently flooded sites are represented: permanent inland deltas; permanent rivers/streams/creeks; seasonal, intermittent, or irregular rivers/streams/creeks; permanent freshwater lakes; seasonal or intermittent freshwater lakes; seasonal or intermittent saline/brackish/alkaline lakes and flats; permanent saline/brackish/alkaline marshes and pools; seasonal or intermittent saline/brackish/alkaline marshes and pools; permanent freshwater marshes and pools; seasonal or intermittent freshwater marshes and pools; non-forested

peatlands; alpine wetlands including meadows and temporary snowmelt waters; tundra wetlands; shrubby-dominated wetlands; freshwater tree-dominated wetlands on inorganic soils; forested peatlands; freshwater springs and oases; geothermal wetlands; and subterranean karst and cave hydrological systems). Finally, nine man-made wetland types (aquaculture ponds; ponds; irrigated land including rice paddies; seasonally flooded agricultural land; salt exploitation sites; water storage areas including impoundments generally more than 8 ha; excavations; wastewater treatment areas; and canals and drainage channels) are also included in the system.

In North America, the Canadian and U.S. wetland classification systems were developed by government agencies interested in wetland conservation and management. The

Table 2 Brief non-technical descriptions of some wetland types in North America.

Wetland type	General description
Marsh	Herb-dominated wetland with standing water through all or most of the year, often with organic (muck) soils
Tidal marsh	Herb-dominated wetland subject to periodic tidal flooding
Salt marsh	Herb-dominated wetland occurring on saline soils, typically in estuaries and interior arid regions
Swamp	Wetland dominated by woody vegetation and usually wet for extended periods during the growing season
Mangrove swamp (Mangal)	Tidal swamp dominated by mangrove species
Peatland, mire, moor, or muskeg	Peat-dominated wetland
Bog	Nutrient-poor peatland, typically characterized by ericaceous shrubs, other woody species, and peat mosses
Fen	More or less nutrient-rich peatland, often represented by sedges and/or calciphilous herbs and woody species
Wet meadow	Herb-dominated wetland that may be seasonally flooded or saturated for extended periods, often with mineral hydric soils
Bottomland	Riverside or streamside wetland, usually on floodplain
Flatwood	Forested wetland with poorly drained mineral hydric soils located on broad flat terrain of interstream divides, common on coastal plains and glaciolacustrine plains
Farmed wetland	Wetland cultivated for rice, cranberries, sugarcane, mints, or other crops

Note: These types may be defined differently in other regions.

Fig. 1 Some examples of North American wetlands: (A) tidal salt marsh, (B) inland marsh, (C) pothole marsh, (D) wet meadow/shrub swamp, (E) northern peatland, (F) bottomland swamp, (G) hardwood swamp, and (H) flatwood wetland.

Canadian system emphasizes wetland origin (class), form, and vegetation in describing the wetland types.^[4] Five wetland classes are recognized as follows: bog, fen, marsh, swamp, and shallow water. Within each class, different forms and types are characterized. Eight general vegetation types are defined by the presence or absence of vegetation (treed, shrub, forb, graminoid, moss, lichen, aquatic bed, and non-vegetated). These types may be subdivided into other types (e.g., treed into coniferous or deciduous; shrub into tall, low, and mixed; graminoids into grass, reed, tall rush, low rush, and sedge; and aquatic bed into floating and submerged). The U.S. Fish and Wildlife Service's wetland and deepwater habitat classification^[5] is the official federal system used for mapping wetlands and for reporting the status and trends of wetlands in the United States. The features separating wetlands include general ecological and physical factors and specific features such as vegetation, soil/substrate composition, hydrology, water chemistry, and human alterations. Classification follows a hierarchical approach with five main levels designated as follows: ecological system (marine, estuarine, lacustrine, riverine, and palustrine), subsystem, class (vegetated: forested, scrub-shrub, emergent, and aquatic bed; non-vegetated: unconsolidated shore, rocky shore, streambed, and reef), subclass, and modifiers. The modifiers are used to describe a wetland's hydrology (water regime), pH and salinity (water chemistry), soils, and the influence of humans and beaver (special modifiers). Common types include estuarine intertidal emergent wetlands (e.g., salt and brackish marshes), estuarine intertidal unconsolidated shore (e.g., tidal flats and beaches), palustrine emergent wetlands (e.g., marshes, fens, and wet meadows), palustrine forested

wetlands, and palustrine scrub-shrub wetlands (e.g., shrub bogs and shrub swamps).

A hydrogeomorphic approach (HGM) to wetland classification has also been developing in the United States.^[16] The HGM system emphasizes the abiotic features important for assessing wetland functions. Seven hydromorphic classes are identified as follows: riverine, depressional, slope, mineral soil flats, organic soil flats, lacustrine fringe, and estuarine fringe. The U.S. Fish and Wildlife Service has adapted the HGM approach to provide additional modifiers to its classification system on a pilot basis. These HGM-type descriptors include landscape position (i.e., lotic, lentic, terrene, estuarine, and marine), landform (i.e., slope, basin, interfluvium, floodplain, flat, island, and fringe), and water flow path (i.e., inflow, outflow, throughflow, bidirectional flow, isolated, and paludified).^[17] These descriptors provide the required information to aid the evaluation of functions of wetlands across watersheds and large geographic areas.

EXTENT OF WETLANDS

Comprehensive wetland inventories do not exist in most countries. There are many inconsistencies among the inventories (e.g., different levels of effort, focus on particular types, and artificial wetlands such as rice paddies are often not included in wetland inventories).^[18] Consequently, comparative analysis is fraught with problems. Nonetheless, Table 3 provides some perspective on the extent of wetlands in many regions. Most of the data came from a series of reports produced for the Bureau of the Ramsar Wetlands Convention.^[6] Globally, estimates for wetlands range from about 750 million ha^[18] to about 1.5 billion ha. Ten countries have over 2 million ha of peatlands alone, with Canada leading at nearly 130 million ha (represents about 18% of the country) followed by the former U.S.S.R. at 83 million ha.^[19,20] About a third of Finland is covered by peatlands (10 million ha). The Pantanal of South America, perhaps the largest wetland in the world, reportedly covers about 200,000 km² (or 2 million ha) during the wet season.^[21]

Wetlands: Biodiversity

Jean-Claude Lefeuvre

Virginie Bouchard

School of Natural Resources, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Wetlands are highly complex ecosystems subjected to a variety of hydrologic regimes, climatic conditions, soil formation processes, and geomorphologic settings. They include swamps, bogs, marshes, mire, fens, salt marshes, mangroves, and other types of ecosystems saturated by water during all or part of the growing season. They are found on every continent, except Antarctica, and in various climes, from the tropics to the tundra. The extent of the world's wetland is generally estimated to be from 7 to 9 million km² or about 4–6% of the earth. The variety of seasonal and perennial wetlands provides environmental conditions for highly distinctive fauna and flora.

ROLE OF HYDROLOGY

Wetlands differ significantly in their water source and seasonal hydrologic regime. Hydrological patterns (i.e., flooding frequency, duration, and hydroperiod) influence physical and chemical characteristics (e.g., salinity, oxygen and other gas diffusion rates, reduction–oxidation potential, and nutrient solubility) of a wetland. In return, these internal parameters and processes control flora and fauna distribution as well as ecosystem functions. Plants, animals, and microbes are often oriented in predictable ways along the hydrological gradient (Fig. 1). Conversely, the biotic component affects the hydrology by eventually modifying flow or water level in a wetland.^[1,2] Species also influence nutrient cycles and other ecosystem functions.^[3]

A LANDSCAPE PERSPECTIVE

Although the hydrology is part of the ecological signature of an individual wetland, wetlands are considered as neither aquatic nor terrestrial systems. They have characteristics from both systems and are defined as ecotones placed under this dual influence.^[4] Because wetlands are located at the interface of multiple systems, they assure vital functions (e.g., wildlife habitats) beneficial at the landscape level. Reduction of wetland area often reduces biodiversity in the landscape.^[2,5] Increases in biodiversity occur when wetlands are created or restored in a disturbed landscape.^[6]

WETLAND FLORA

Wetland plants are adapted to a variety of stressful abiotic conditions (e.g., immersion, wave abrasion, water level

fluctuation, and low oxygen conditions). Identical adaptations to common environmental features have led taxonomically distinct species to sometimes look similar in terms of morphology, life cycle, and life forms.^[7] Traditionally, wetland plants have been classified into groups of different life forms, primarily in relation with hydrological conditions. Helophytes are defined as plant species with overwintering buds in water or in the submerged bottom.^[8] They are differentiated from hydrophytes in that their vegetative organs are partially raised above water level.^[8] Hejny's classification is based on relatively stable vegetative features that determine the ability of wetland plants to survive two unfavorable conditions, namely cold and drought.^[7] This classification uses the types of photosynthetic organs present in both the growth and flowering phases. Other classifications include both life form and growth form. When a species has a range of growth form, it is classified under the form showing the greatest achievement of its potential.^[7]

Plant communities in wetlands can be more or less homogeneous, mosaic-like, or distributed along a gradient resulting in a clear zonation of species. A gradient exists if one or several habitat parameters change gradually in space. This phenomenon is common in freshwater marshes that present a gradient of water depth and water-saturated soils (Fig. 1). Such a gradient is often accompanied by differences in peat accumulation that is influenced by waves or currents. General principles of the zonation of aquatic plants have been largely described.^[7,9,10] Littoral vegetation can belong to several types of communities, which derived from the general principle that, from deeper water to the shore, we may expect successively submergent, floating, and emergent macrophytes. The most important habitat factor is water depth, depending on slope and

Fig. 1 Species distribution along the hydrological gradient in a freshwater marsh.

peat accumulation.^[10] Other factors may be poor irradiance caused by high turbidity or exposure to waves or flow.^[7,10]

Riparian ecosystems are found along streams and rivers that occasionally flood beyond confined channels or where riparian sites are created by channel meandering in the stream network. Riparian or bottomland hardwood forests contain unique tree species that are flood tolerant. Species distribution is associated with floodplain topography, flooding frequency, and flooding duration.^[11,12] In Southeastern U.S. bottomland, seasonally flooded forests are colonized by *Platanus occidentalis* (sycamore), *Ulmus americana* (American elm), and *Populus deltoides* (cottonwood) and are flooded between 2% and 25% of the growing season (Fig. 1). Other species such as *Fraxinus pennsylvanica* (green ash), *Celtis laevigata* (sugarberry), and *Carya aquatica* (water hickory) are colonized bottomlands that are flooded by less than 2% of the growing season.^[11] Freshwater marshes are dominated with emergent macrophytes rooted in the bottom with aerial leaves (i.e., helophytes). Species such as *Typha* (cattail), *Phragmites* (reed grass), and *Scirpus* (bulrush) are often clonal.

A plant community is usually organized in sequence of patches that are dominated by one species. The second plant groups are the rooted plants with floating leaves (*Nymphaeid*). Lotus (*Nelumbo*) and water lilies (*Nymphaea*) have very identical morphology (i.e., similar leaves and flowers), but a genetic analysis showed that lotus is more closely related with plane tree than with water lilies.^[10] Submerged plants include elodeids (i.e., cauline species whose whole life cycle can be completed below the water surface or where only the flowers are emergent) and isoetids (i.e., species growing on the bottom whose whole life cycle can be completed without contact with the surface). Submerged species include species such as coontail (*Ceratophyllum demersum*) and water milfoil (*Myriophyllum* spp.). Plant species found in salt marshes are called halophytes (i.e., plants that complete their cycle in saline environments). A saltmarsh can be divided into low, middle, and upper marsh, according to flooding frequency and duration. Each zone is dominated by different plant species according to their tolerance to saline immersion.^[10]

A dominant competitive species—often a clonal species—can modify the theoretical zonation. Change in water chemistry (i.e., eutrophication) or hydrology may favor a particular species over the natural plant community. Highly competitive species are often invasive and aggressive in displacing native species. The expansion of *Phragmites australis* into tidal wetlands of North America causes a reduction in biodiversity as many native species of plants are replaced by a more cosmopolitan species.^[13] In riparian ecosystems, biodiversity is usually higher in the intermediate zones, whereas it is lower upstream and downstream (Fig. 2). The percentage of exotic species is low in upstream areas, but can represent up to 40 in downstream zones (Fig. 1).^[14]

WETLAND FAUNA

Diversity of vertebrate and invertebrate species is the result of a diverse community composed of resident and transient species, which use the space differently and at various times of day and year. The density and variety of animal populations at a particular wetland site are also explained by climatic events that affect geographic areas on a large scale; e.g., the population of waterfowl during winter is largely dependent on climate variations in the northern part of the continents.^[15]

Resident species are often dependent on the type of vegetation. Animal communities are generally distributed along a zonation pattern, parallel to the plant communities,

which is driven by the hydrological gradient. A few species depend entirely on a single plant species for their survival. One beetle (*Donacia* spp.) may depend on reeds, at least during its larval stage where another beetle (*Galerucella* spp.) uses only water lilies as their habitat and diet. For many other residents, their habitats extend to several plant communities during their life span. It is generally the case for many vertebrates such as amphibians, rodents, passerines, and waterfowl.

Many amphibian species depend on wetland or riparian zones for reproduction and larval stage. Likewise, wet meadows are necessary as a reproduction zone and nursery for a number of freshwater fishes. About 220 animals and 600 plant species are threatened by a serious reduction of wetlands in California, and the state's high rate of wetland loss (91% since the 1780s) is partly responsible.^[15] Many waterfowl species are sensitive to areas of reduction, patch size and distribution, wetland density, and proximity to other wetlands.^[16] When the Marais Poitevin (France), one of the principal wintering and passages sites for waterfowl in the Western Europe, underwent agricultural intensification in the 1980s, the population of ducks and waders declined tremendously. This decline was partly due to a 50% reduction of wet meadows between 1970 and 1995, primarily caused by the conversion to arable farmlands.^[17] Thus, maintenance of biodiversity depends on the existence of inter connections between wetlands and between aquatic and terrestrial ecosystems. In fact, some authors have pointed out that increase in biodiversity occurs when wetlands are created or restored in a disturbed landscape.^[6,18]

CONCLUSION

Despite the importance of wetlands, conservation efforts have ignored them for a long time. It is urgent to conserve the existing wetlands and also to restore and create wetland ecosystems. A wide range of local, state, federal, and private programs are available to support the national policies of wetland “No Net Loss” in the United States and around the world. From a biodiversity perspective, wetland protection policies may not be working because restored or created wetlands are often very different from natural wetlands.^[19] Created wetlands often result in the exchange of one type of wetland for another and result in the loss of biodiversity and functions at the landscape level.^[19] We know that it takes more water to restore a wetland,^[20] even if an important place should be given to the ability of self-design of wetland ecosystems.^[21]

Wetlands: Carbon Sequestration

Virginie Bouchard

Matthew Cochran

School of Natural Resources, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

The primary production in wetland ecosystems is greatly enhanced by hydrological fluxes, which leads to high biomass, primary production, and accretion rates. The carbon (C) is either fixed stored in standing biomass, released by soil decomposing microorganisms, or stored in soil sediments. With the continual destruction of wetlands worldwide, more of this sequestered C is released to the atmosphere. The protection of wetlands will preserve the amount of C already stored in these ecosystems.

INTRODUCTION

The increase in the concentration of “greenhouse gases” in the troposphere and its relation to human activities is well documented.^[1] Carbon (C) fixation via photosynthesis and C release during decomposition have always been two important processes regulating the concentrations of carbon dioxide (CO₂) and methane (CH₄) in the atmosphere, even in prehistoric and preindustrial times. In addition to these internal processes, wetland ecosystems receive and release organic C through hydrologically driven mass fluxes. Thus, the C pool within any wetland ecosystem is in balance between primary production, microbial decomposition, and C fluxes within interconnected ecosystems (Fig. 1). Wetlands play a particularly complex role in controlling greenhouse gases, as these ecosystems are intimately associated with all aspects of the production and consumption of both CO₂ and CH₄ (Fig 2).

C SEQUESTRATION WITH PRIMARY PRODUCTION

The concept of primary productivity is directly related to the ideas of energy flow in ecosystems. A portion of the photosynthetically active radiation, which is radiation in the 400–700 nm wave band, received by an ecosystem is absorbed by autotrophic organisms (photosynthetic plants and microorganisms). The absorbed energy is reradiated, lost as latent heat, or stored by the activity of photosynthesis in organic substances. This last flow of energy corresponds to net primary production (NPP). Fundamental ecological questions relating to the global C budget, the location of the missing C sink, and predictions of global climate change rely on obtaining good estimates of NPP.

Wetland ecosystems can have very high standing biomass values and correspondingly high NPP.^[2,3] The annual aboveground NPP of macrophytes is reported to be up to 5 kg dry matter in the most productive sites.^[2] This production varies according to species, wetland type, and latitude^[2,3] and is often well correlated with the maximum aboveground standing crop. Belowground production is much more difficult to estimate because roots and rhizomes grow and die at different rates and times and because materials are translocated to and from shoots. The ratio of belowground to aboveground production can vary from 0.2 to 2.5 according to various studies.^[2] The connectivity of a wetland to hydrological fluxes (i.e., saltmarshes flooded by tides, coastal freshwater marshes flooded by seiche, and riparian bottomland forests flooded by floods) is one of the most important factors enhancing primary productivity.^[4]

Net C capture from herbaceous vegetation is minimal compared to the long-term accumulation of C in bottomland hardwood forests. At the end of the growing season, most of the C trapped in the biomass of herbaceous macrophytes is found in dead plant litter and is released as CO₂ or CH₄ during decomposition or exported as dissolved or particulate organic matter to adjacent systems. Bottomland hardwood forests store C in tree biomass for a much longer period of time. The productivity of bottomland forest ranges between 200 and 2000 g dry organic matter per year.^[5]

C SEQUESTRATION IN SOILS

C fixed in photosynthesis either remains in the sediment as C accretion or is decomposed to CO₂ and CH₄ by a suite of fermentative microbes involved in soil organic matter decomposition. A diversity of biological, chemical, and physical mechanisms is also known to selectively

Fig. 1 Conceptual model showing the fluxes of organic C in wetlands.

“protect” different pools of soil organic matter from decomposition by soil microorganism. Most of the recalcitrant C destined for sediment accretion is derived from heavily lignified biomass. Organic soil is a result of the anaerobic conditions created by standing water or poorly drained conditions.

C is even better protected in acidic environments, in marine sediments, and under low temperatures. Peat accumulation is a result of reduced oxidation of the biomass produced in wetlands. The northern peatlands have accumulated 25–38 Pmol C since the last glaciation, equivalent to 50–70% of the total amount of C

present in the atmosphere.^[6] Peat accumulation is greater in bogs than in fens due to differences in nutrient availability. Decomposition rates are enhanced in minerotrophic fens receiving nutrients from adjacent mineral soils relative to ombrotrophic bogs, which are fed only by rainwater.

Canadian wetland soils store about 154 GtC, representing an average of 60% more C than what is stored in Canadian forests (95 Gt C in biomass and soils), which in turn is two orders of magnitude larger than the agricultural soil C pool^[7] (Table 1). Peatlands are a sink for between 20 and 30 g C m⁻² yr⁻¹, which means that Canadian peatlands sequester about 0.03 Gt C yr⁻¹ (Table 1). The sequestration rate of peatlands is smaller than the rate computed for boreal forests. However, the major difference between forests and peatlands is that a forest sink is transient and cannot be sustained continuously. If peatlands also have a theoretical limit to growth, it is reached only after many thousands of years.^[8] However, the fluxes of CO₂ and CH₄ from peatlands vary highly according to seasons, years, species, and sites. Interannual measurement schemes—such as those that have been developed for forest ecosystems with the Ameriflux and Euroflux programs—are needed to establish more precise fluxes of CO₂.

IMPACT OF HUMAN ACTIVITIES ON C STORAGE

Rates of plant production are limited by phosphorus supply in freshwater systems and by nitrogen (N) supply in

Fig. 2 View of a freshwater wetland.

Table 1 Summary of C stocks and fluxes in Canadian wetlands/peatlands, forests, and agricultural fields.

Land use	Area (km ²)	C stock (Gt C)	Fluxes (Gt C yr ⁻¹)	Potential duration (years)
Peatlands/wetlands soils	1.24 × 10 ⁶	154	-0.03	1000 (?)
Forests	5.15 × 10 ⁶	95	-0.2	50
Agriculture fields	0.45 × 10 ⁶	6	0.0034	50

Source: Adapted from Roulet.^[7]

saltwater and terrestrial systems.^[9,10] An excess of nutrients leads to an increase of both primary production and decomposition in terrestrial systems.^[11] Decomposition rates increase, however, at a slower rate than primary production, leading to a potential increase of C storage in soil.^[11] In wetlands, little is known about the effect of excess nutrients on the denitrification process, which is directly linked to the amount of soil organic matter.^[12]

Wetlands have been drained on all continents due to human development. Rapid changes occur in organic soils after drainage as aerobic microbial decomposition is enhanced, releasing large amounts of CO₂ into the atmosphere. C losses can lead to subsidence of the soil profile, changes in bulk density, and decreases in C content of the remaining soil.

CREATION OF WETLANDS TO SEQUESTER C

Wetlands—particularly bottomland hardwood forests—are considered as potentially excellent “C sinks” because they take CO₂ out of the atmosphere and store it in living plant tissues and soil organic matter. Wetland creation might provide an opportunity to positively address wetland habitat losses while also addressing global warming.^[8,13] However, a question, remains: are we capable of constructing wetlands that function in similar ways as natural wetlands? How well these created and constructed wetlands mimic natural wetlands is being debated.^[14,15]

Various studies have indicated that created wetlands might not function in the same capacity as adjacent reference wetlands.^[16] In created *Spartina alterniflora* salt marshes, vegetation rapidly achieves 100% cover although soil nitrogen and organic matter are slow to accumulate. Salt marshes constructed in North Carolina have lower soil organic carbon (SOC) and lower total N reservoirs than a 2000-year-old natural marsh.^[16]

Their C accumulation rates are similar to those of reference sites, but N accumulation rates are higher; thus, C/N ratios have declined over time. In Oregon, 95 restored freshwater marshes had lower soil organic matter than natural marshes and no evidence of accumulation.^[17]

Because bottomland hardwood forests combine both a long-term C storage in tree biomass and a slow release of SOC under flooded conditions, they are considered as

excellent ecosystems that could potentially be used to sequester C. The restoration of bottomland hardwood forests on marginal agricultural lands in the Mississippi River Valley offers significant net C sequestration in the south-central region of the United States.^[13] However, hardwood plantings have problems with slow initial growth and excessive early mortality rates. The use of herbaceous weed control and bedding may offer the potential to overcome these difficulties.^[13] Under the initiative of the U.S. Department of Energy, an 80-acre pilot study is underway in Louisiana. Abandoned marginally productive agricultural fields were planted in January 1997 with seven bottomland hardwood species. Following planting, the site will be monitored for planting success and survival. When the trees attain heights of >4.5 ft, growth data and C sequestration per acre will be calculated.^[13]

CONCLUSION

The primary production in wetland ecosystems is greatly enhanced by hydrological fluxes, which leads to high biomass, primary production, and accretion rates. The C is either fixed stored in standing biomass, released by soil decomposing microorganisms, or stored in soil sediments. With the continual destruction of wetlands worldwide, more of this sequestered C is released to the atmosphere. The protection of wetlands will preserve the amount of C already stored in these ecosystems.

The creation and restoration of new wetlands will certainly contribute to the sequestration of C and should be considered as one way to mitigate greenhouse emissions.

Wetlands: Conservation Policy

Clayton Rubec

Center for Environmental Stewardship and Conservation, Ottawa, Ontario, Canada

Abstract

Meeting the challenge of conserving wetlands requires comprehensive national policies to provide a foundation for domestic action and a framework for international and national cooperation. Such policy is valuable as countries seek to address the management and habitat requirements for wildlife and other natural resources, such as soil and water, as well as human needs. The implementation of a national wetland policy is a key feature of the wise use principles of the Convention on Wetlands of International Importance (the Ramsar Convention). However, such policy seems an elusive goal for many of the 145 nations that (May 2005) are Contracting Parties to this global environmental treaty.

INTRODUCTION

Responding to recommendations by the Convention, in 1998–1999, the author led a team of writers in preparing guidelines for developing and implementing national wetland policies.^[1] These policy guidelines complement the Convention's guidance on wetland legislation.^[2] This entry provides highlights of the guidelines and reports on the status of wetland policy development around the world, effective mid-1999.

RELATIONSHIP BETWEEN POLICY AND WISE USE

The wise use principles are a hallmark of the Ramsar Convention. "Wise use" applies not only to sites listed as wetlands of international importance (as of May 2005 covering over 125 million hectares at 1429 sites) but also to all wetlands in the territory of Contracting Parties. These *principles* help Contracting Parties improve institutional and organizational arrangements, address legislative and policy needs, increase knowledge and awareness of wetland values, inventory and monitor the status of wetlands, identify program priorities, and develop action plans for specific sites as components of a national wetland policy.

The formulation of national wetland policies sometimes involves a lengthy and complex process. Political, jurisdictional, institutional legal, and financial constraints affect policy formulation in addition to social and economic factors that continue to contribute to wetland loss, while the policy process is under way.

WHAT ARE WETLAND POLICIES AND ARE THEY NEEDED?

A policy can simply be a document. However, making is also a process involving consensus building, the encapsulation of

ideas and commitments, implementation, accountability, and review complemented by legislation, strategies, and operational programs. It is a mechanism for an administration to capture the public will or mandate on an issue and refine it with its own vision.

A National Wetland Policy is nationwide in scope, but it may be developed at several levels of government. In Australia and Canada, e.g., both the federal government and state/provincial governments have developed wetland conservation policies. This reflects the federal nature of these two nations, wherein constitutional authority for natural resources management (including wetlands) is divided between the levels of government.

Wetlands are seldom explicitly covered in other natural resource management policies such as for water, soil, forest, land, or agriculture at a national level. Development of a "stand-alone" wetland policy and/or strategy can be an important step in recognizing and solving wetland problems. A wetland policy recognizes wetlands as ecosystems requiring different approaches not masked under other sectoral management objectives. The articulation of goals and objectives for these ecosystems identifies clear responsibilities of the government and a public expectation that the government will deliver these commitments.

Wetland policy objectives need to focus on a variety of themes, as they become the image of the policy. However, the practical implementation of the policy may result in only one or two of these objectives receiving the greatest public attention. For example, Canada's announcement of its federal wetland policy in 1992 contained seven objectives, but "no net loss of wetland functions" has proven to be its catch phrase.

THE GUIDELINES

The guidelines review the key steps and issues that may arise in both developing and implementing a National

Wetland Policy. These include over 20 detailed sections defining the purpose of such an initiative, organizing a suitable process, deciding how to present the content of the policy document, and developing strategies for implementation and monitoring. The text is complemented by the following seven wetland policy essays: 1) *defining stakeholders*; 2) *consultations*; 3) *wetland policies within a federal state*; 4) *sectoral policies and legislation*; 5) *compliance strategies*; 6) *role of nongovernment organizations*; and 7) *the development and coordination process*. The guidelines provide a reference against which all nations can review their wetland action plans and strategies at the national level.

A team of contributors with governmental or non-governmental work experience and expertise in wetland policy development prepared the guidelines. The team included writers from Ramsar national authorities in Australia, Canada, Trinidad and Tobago, Uganda, and the United States. Contributors from BirdLife International, University of Massachusetts, IUCN Environmental Law Centre, and Wetlands International were also involved.

Implementation Strategies

A National Wetland Policy includes specific implementation strategies that demonstrate the priorities of the

government and also fosters the cooperation and involvement of other interests. Linkages between these strategies and national water, soil, biodiversity, and sustainable development policy initiatives are explored in the guidelines.

An analysis of the strategies used in selected National Wetland Policies is summarized in Table 1. These include the policies/action plans of Australia, Cambodia, Canada, Columbia, Costa Rica, Finland, France, Jamaica, Malaysia, Peru, Trinidad and Tobago, and Uganda. These initiatives have many common strategic approaches as follows: 1) ensuring public awareness and education; 2) developing cooperation and partnerships between levels of government from national to local; 3) developing and supporting legislation and interrelated land and water use policies and programs; 4) implementing wetland site management responsibilities; 5) developing a sound basis for the policy through scientific research and expertise; 6) developing institutional and financial capacity for policy implementation; and 7) meeting international commitments. These strategies have been drafted to evoke a clear vision and acceptance across the nation.

Global Review of the Status of Wetland Policies and Strategies

Significant progress is evident globally in the development of National Wetland Policies since the Ramsar Convention focused attention on this issue in 1987.^[1,3,4] Meetings of the Contracting Parties every 3 years allow regular review of the status of wetland policies. The Contracting Parties last met in November 2002 when there were 123 Contracting Parties, while (May 2005) there are 145 Contracting Parties.

Policies

As of November 2002, 60 (56%) of the 107 Ramsar Contracting Parties that submitted national reports to the Eighth Meeting of the Contracting Parties to the Convention on wetlands indicated that they were engaged in development or implementation of a National Wetland Policy. Between 1987 and 2002, the number of nations with a National Wetland Policy officially adopted grew from 0 to 41. An additional 19 nations indicated that a National Wetland Policy was in draft or under consideration. However, 47 (44%) of the Ramsar Contracting Parties did not yet report any actions being taken in support of National Wetland Policy development. A number of nations, particularly those with a commonwealth or federal makeup, reported wetland policies and strategies at the subnational level also. National Wetland Policies have also been called a “national wetland strategy” or an “action plan.”

Table 1 Implementation strategies in selected national wetland policies.

Country	1	2	3	4	5	6	7	8	9	10	11	12
Australia	X	X	X	X	X	X						
Cambodia	X	X	X	X	X	X	X					
Canada	X	X	X	X	X	X						
Colombia	X	X	X	X	X	X	X	X				
Costa Rica	X	X	X	X	X	X	X					
Finland	X	X	X	X	X	X	X					
France	X	X	X	X	X							
Jamaica	X	X	X	X								
Malaysia	X	X	X	X	X	X	X	X	X			
Peru	X	X	X	X	X	X						
Trinidad and Tobago	X	X	X	X	X	X						
Uganda	X	X	X	X	X	X	X	X				

Note: Policy strategies: 1) management of national wetland networks; 2) integration with other policies such as water, soil, and forests; 3) public awareness and education; 4) partnerships; 5) science, monitoring, assessment, and research; 6) international commitments; 7) managing special sites; 8) administration and institutions, capacity building; 9) enforcement, regulation, and legislation; 10) financial mechanisms; 11) restoration of degraded sites; and 12) sustainable use and conservation.

Table 2 Evolution of Ramsar Convention on national wetland policies/strategies.^a

Status of national wetland policies or strategies	1987 Regina COP3	1990 Montreux COP4	1993 Kushiro COP5	1996 Brisbane COP6	1999 San José COP7	2002 Valencia COP8

No policy/strategy activity reported	15	40	36	65	72	47
Number of national reports tabled at this COP	17	45	51	92	98	107

^aAs of May 2005, the Ramsar Convention had 145 Contracting Parties.

Table 2 summarizes the status of the development and adoption of National Wetland Policies from 1987 to November 2002. This table was developed by reviewing the reports and conference papers that summarize the activities of the Convention every 3 years by each country. In 1987, only two nations indicated that they were involved in developing any sort of National Wetland Policy/Strategy. By 2002, this number grew to at least 60 nations. Table 3 summarizes the countries by Ramsar's regions (Africa, Asia, Europe, Neotropics, North America, and Oceania) that have either a *national wetland policy* or *national wetland strategy* adopted, being drafted or considered up to May 2005.

CONCLUSION

The development and implementation of National Wetland Policy in the 145 countries that have acceded to the Ramsar Convention is proceeding throughout the world. The Convention's Wise Use Principles and Guidelines on National Wetland Policy,^[1] complemented by guidelines for wetland legislation,^[2] are effective tools in fostering the completion and use of National Wetland Policies and Strategies as important cornerstones of this Convention. At least 56% of the Ramsar Convention's Contracting Parties are continuously implementing or developing National Wetland Policies/Strategies.

One of the most interesting aspects of the Ramsar Convention is its capacity to foster sharing of experience. Interchanges by wetland policy experts are occurring internationally that involve short-term invited visits or sabbaticals, informal exchange of documents, confidential advice, and review of draft policy. Consultation workshops, working with non-government groups, meeting with senior government officials, exploring funding mechanisms, and assisting in drafting the text, have also been involved. Experience gained in one nation's development of these policies

Table 3 Summary of national wetland policies and strategies by Ramsar regions (2002).

Ramsar region	National Wetland Policy or Strategy Adopted by Government	National Wetland Policy or Strategy in Preparation or Under Consideration
Africa	Congo Republic, Côte d'Ivoire, Senegal, South Africa, and Uganda	Algeria, Botswana, Burkina Faso, Chad, Comoros, Democratic Republic of the Congo, Egypt, the Gambia, Ghana, Guinea, Kenya, Malawi, Mali, Morocco, Namibia, Niger, Togo, and Zambia
Asia	Indonesia, Japan, Thailand, and Vietnam	Bangladesh, Cambodia, China, Georgia, India, Republic of Korea, Malaysia, Mongolia, the Philippines, Russia, ^a and Turkey
Europe	Belgium, Bulgaria, Denmark, Estonia, Finland, France, Greece, Iceland, Malta, Monaco, the Netherlands, Norway, Romania, Sweden, Switzerland, and the United Kingdom	Austria, Belarus, Croatia, Czech Republic, Germany, Hungary, Ireland, Italy, Latvia, Lithuania, Poland, Portugal, Russia, ^a Slovak Republic, Slovenia, Ukraine, and Federal Republic of Yugoslavia
Neotropics (Central and South America and Caribbean)	Colombia, Costa Rica, Jamaica, Peru, and Trinidad and Tobago	Argentina, Bahamas, Chile, Ecuador, Guatemala, Honduras, Nicaragua, Panama, Paraguay, and Venezuela
North America	Canada and the United States	Mexico
Oceania (Australia and Pacific)	Australia and New Zealand	—

Wetlands: Economic Value

Gayatri Acharya

World Bank, Washington, District of Columbia, U.S.A.

Abstract

The valuation of wetland goods and services has become an important tool of land use analysis and water resource management. With improved understanding of how benefits may be derived directly or indirectly from wetlands, economic tools have been applied to elicit values associated with these benefits. This information is increasingly being used to inform public policy and investment decisions.

INTRODUCTION

Wetlands have historically been and continue to remain centers of human civilization and economic activity, supporting vast populations both directly and indirectly. As such, wetlands have been used, transformed, or converted over time, and their capacity in some cases has been diminished by the impacts of land use changes.

The conversion of multiple use ecosystems to single land uses may signify a welfare loss through reduced access to, or availability of, valuable goods and services. Whether or not such conversions are merited can be assessed only with sufficient information on the relative efficiency of converting or conserving the wetland ecosystem vis-à-vis alternative land uses. Economic values are a measure of how much people are willing to pay for and how much better or worse off they would consider themselves to be as a result of changes in the supply of different goods and services. Valuation provides a means of quantifying the benefits that people receive from wetlands. The net benefits of investing in land uses that are compatible with wetlands conservation, relative to those economic activities, which contribute to wetlands degradation, can then be assessed. Values generated through economic analysis are limited by their inability to capture intrinsic values associated with wetlands and the level of understanding, both economists and natural scientists have, with regard to the level of use of goods and services, and variability in the natural system. Furthermore, economic values measure preferences and welfare impacts associated with changes in the natural system or the availability of a service or product, but they do not, in themselves, suggest anything about inter- or intra-generational distributional effects of conservation or development investments.

Wetland goods and services are also particularly difficult to value. This is because: 1) many goods are not marketed but traded or consumed directly; 2) wetland services such as water quality or groundwater recharge often occur in areas away from the physical location of the wetland and

may not be easily attributable to the wetland; 3) many wetlands are transboundary resources and data on the use and consumption of goods and services are difficult to obtain; and 4) many wetlands are public property. For these and other related reasons, the economic benefits generated by wetlands and the economic costs associated with wetland degradation or loss are frequently unknown and omitted in project or policy analysis. As a result, the potential of wetlands to be acknowledged as contributors to economic growth, income generating activities, and as sources of goods and services, has been underestimated in many parts of the world, resulting in the loss of valuable species, services, and livelihoods. Further, with growing recognition of the links between ecological and economic functions of these ecosystems, there are increasing efforts being made by researchers and planners to factor in the value of the goods and services of wetlands in economic decision making.

ECONOMIC VALUES OF WETLANDS

Wetlands cover an estimated 6% of the world's land surface and may be of various types such as marshes, floodplains, freshwater ponds, lakes, swamps, etc. While these ecosystems are associated with a diverse and complex array of direct and indirect uses, the precise functions and benefits of a specific wetland can be determined only after careful study of the hydrological, physical, and biological characteristics of the site, over a period of time. Mitsch and Gosselink^[1] have long highlighted the importance and complexity of these ecosystems, noting that when trying to understand their value "one must consider whether the values of wetlands are based on biological populations living next to and within the wetlands, the wetland ecosystem itself, or the entire biosphere of which wetlands are a small part."

Increased knowledge of the direct or indirect benefits attributed to these ecosystems has resulted in mounting

concern about the state of the world's wetlands and an increased focus on how to value these ecosystems. As noted by Barbier,^[2] valuing ecosystem services requires two specific sources of knowledge, namely: 1) the ecological processes, components, and functions that generate useful services and 2) the way in which these services translate into specific benefits.^[1] Since the economic value of an ecosystem service (or good) is determined by the contribution it makes to maintain the present level of human well-being, it is calculated as a measure of a change in well-being, or *social welfare*. Therefore, valuing a good or service requires us to study the change in a person's welfare due to a change in the availability of the resource. Economic value expressed in currency units is the monetary expression of the tradeoff between identified alternative land uses (see the work of Freeman^[3] among others for more on valuation theory).

To fully assess these tradeoffs, the ultimate goal of valuation should be to assess the total economic value (TEV) of a system. TEV is defined as the sum of use value plus existence value where use value is comprised of: 1) direct use value (consumptive or non-consumptive); 2) indirect use value; and 3) option value. Box 1 defines each of these values while Fig. 1 shows how direct and indirect benefits can be identified in a wetland system. While valuation attempts to take account of all the components of the total economic benefit of wetlands, it is generally constrained by data availability, and therefore, partial valuation studies are more common (see the work of Barbier^[4] for more on the differences in total and partial valuation).

Direct uses include the use of the wetland for water supply and harvesting of wetland products such as fish and plant resources. Commonly recognized values of wetlands include those captured from the use of raw materials and physical products that are generally used in economic

BOX 1: TYPES OF BENEFITS VALUED BY ECONOMIC VALUATION TECHNIQUES.

Direct benefits: These include the raw materials and physical products that are used directly for production, consumption, and sale including those providing energy, shelter, foods, water supply, transport, and recreation.

Indirect benefits: These include ecological functions which maintain, protect, and support natural and human systems through services such as maintenance of water quality, flow and storage, flood control and storm protection, nutrient retention, and micro-climate stabilization, and other productive and consumptive activities.

Option benefits: These refer to the premium placed on maintaining a pool of wetlands species and genetic resources for future uses such as for leisure or in commercial, industrial, agricultural and pharmaceutical applications and water-based developments, some of which may not be used or known in the present but may be used in the future.

Existence benefits: The intrinsic value of wetlands species and areas regardless of their current or future use possibilities, such as cultural, aesthetic, heritage and bequest significance.

Fig. 1 Identifying direct and indirect benefits in a wetland system.

activities such as fisheries, water supply, and agriculture. Where wild foods, grasses, bird life, and other naturally occurring species are exploited for significant economic returns, such uses are also easily identifiable and may be valued in existing markets.

Direct uses, however, represent only a small proportion of the total value of wetlands, which generate economic benefits in excess of just physical products. *Indirect benefits* are derived from environmental functions that wetlands may provide, depending on the type of wetland, soil, and water characteristics, and associated biotic influences. Wetland functions are defined as a process or series of processes that take place within a wetland, including habitat and hydrological and water quality functions. Such functions have an economic value if they contribute to economic activity and enhance human welfare.

VALUING WETLANDS GOODS—TECHNIQUES AND EXAMPLES

A combination of the available techniques used to value environmental goods and services can be used to approximate a partial or total value of any one ecosystem, taking care that we can identify the various components of the system and have adequate economic and ecological data to do so. The following methods have been used in valuing wetland resources:

Market prices: to estimate economic values for ecosystem products or services that are bought and sold in markets.

Change in productivity: to estimate economic values for ecosystem products or services that contribute to the production of marketed goods or services.

Travel cost: to estimate economic values associated with ecosystems/sites used for recreation based on the assumption that the value of a site is reflected in how much people are willing to pay to travel to visit the site.

Hedonic pricing: to estimate economic values for ecosystem or environmental services that directly affect market prices of some other good, e.g., housing prices may reflect the value of local environmental attributes or amenities.

Contingent valuation method: to estimate economic values for products and ecosystem services. This can be used to estimate non-use values by asking people to directly state their willingness to pay (WTP) for specific environmental services, based on hypothetical scenarios or contingent markets.

Contingent choice, contingent ranking, contingent behavior: to estimate economic values for products and for ecosystem services by asking people to make tradeoffs between sets of ecosystem or environmental services or characteristics.

Benefit transfer: to infer economic values by transferring benefit estimates from localized studies to similar areas under similar market conditions.

Damage cost avoided, replacement cost, and substitute costs: to estimate economic values based on costs of avoided damages resulting from lost or diminished ecosystem services, replacing ecosystem services, or providing substitute services.

Examples of how these techniques have been applied to elicit values of various wetland benefits are given in Boxes 2 and 3 and in Table 1. These studies illustrate the range of values associated with different types of goods and services, wetlands provide.

In some parts of the world, the benefits of protecting natural watersheds and river systems are being recognized and acted upon through government decisions. For

BOX 2: USING CONTINGENT VALUATION AND TRAVEL COST METHODS TO ASSESS THE RECREATIONAL VALUE OF LAKE NAKURU, KENYA.

Lake Nakuru National Park is an important international tourist destination in Kenya. Fees currently charged to enter the park underestimate the total value that tourists place on the wetland and its component species, especially flamingos. A travel cost survey of visitors elicited information about length of stay, travel costs, place of origin, and visitation rates, distinguishing between resident and nonresident tourists. The contingent valuation survey used in this study asked visitors what their personal total costs of travel were; how much they would be willing to increase their expenditures to visit the park; how much they would contribute to a fund to clean-up and control urban pollution affecting the park; and how much they would contribute to a project to conserve flamingos. The survey also asked respondents for the minimum reduction in trip costs that they would be willing to accept should there be no flamingos. Results suggests that the annual recreational value of wildlife viewing in Lake Nakuru National Park was between U.S.\$7.5 and \$15 million and over a third of this value was accounted for by the Willingness to Pay for Viewing flamingos.

BOX 3: VALUING THE HADEIJA NGURU WETLANDS, NIGERIA.

In the Hadeija-Jama' are floodplain region in northern Nigeria, more than one half of the wetlands have already been lost to drought and upstream dams. Ecosystem valuation has been used in this area to weigh the costs and benefits of development projects that would divert some more water away from the floodplain for irrigated agriculture in upstream areas. The net benefits of such a diversion are estimated at U.S.\$29 per hectare. In comparison, the floodplain, under the present flooding regime, provided U.S.\$167 per hectare in benefit to a wider range of local people engaged in farming, fishing, grazing livestock, or gathering fuelwood and other wild products—benefits that would be greatly diminished by the project.

A study of the groundwater recharge function of the wetlands confirms furthermore that the wetlands play an important role by maintaining groundwater recharge in the floodplain. Groundwater recharge supports irrigated agricultural production in the floodplain. Irrigated agriculture using water from the shallow groundwater aquifer has a value of 36,308 Naira (U.S.\$413) per hectare for the study area. A value of at least 2863 Naira or U.S.\$32.5 per farmer per dry season or U.S.\$62 per hectare is attributable to the present rate of groundwater recharge. In terms of maintaining water supply resources, the value of the recharge function is 1,146,588 Naira or U.S.\$13,029 per day for the wetlands.

Source: Adapted from Barbier & Adams,^[4] Acharya,^[6] and National Research Council.^[7]

example, the city of New York found that it could avoid spending U.S.\$6–8 billion in constructing new water treatment plants by protecting the upstate watershed that has traditionally provided these purification services. Based on this assessment, the city invested U.S.\$1.5 billion in protecting its watershed by buying land around reservoirs and providing other incentives for land use.^[8] This decision ensures that in addition to getting a relatively cheap treatment system for its water supply, the city also maintains the watershed for recreation, wildlife habitat, and other ecological benefits derived from a healthy ecosystem. Similarly, to restore balance within the Murray–Darling river basin, the Australian government plans to purchase U.S.\$3.2 billion's worth of water rights over a period of 10 years. This will restore approximately 2750 billion liters of water each year to the Murray–Darling basin river system and its wetlands. The ambitious Comprehensive Everglades Restoration Plan (CERP) aims to achieve ecological restoration by reestablishing hydrologic characteristics as close as possible to their predrainage conditions in what remains of the Florida Everglades ecosystem. The CERP, to be implemented over three decades, includes more than 40 major projects and 68 project components to be constructed at an estimated cost of U.S.\$10.9 billion in 2004 dollars (<http://www.evergladesrestoration.gov>).

A growing literature on wetland valuation has contributed to our understanding of how valuation could influence land use policy and investment decisions. WTP for the services offered by wetlands in Taiwan^[9] and Korea,^[10] mangroves in Micronesia,^[11] marine parks in the Seychelles.^[12] Studies also illustrate the regional economic impacts of continuing wetland loss. With increased

understanding of the benefits associated with wetland ecosystems, the rehabilitation and restoration of wetlands is also increasing across the globe. The Malian government is working to restore the inner Niger River Delta which supports the livelihoods of millions of people in Mali, and has been subjected to severe degradation. Similarly, Tanzania is looking to reverse the degradation of Lake Victoria which supports 46 million inhabitants and the world's largest freshwater fishery.

Some caveats to valuation also apply. A number of papers have attempted to value the world's ecosystems, some by extrapolating localized studies of specific resource losses to capture the impact of a global loss of such resources. Even if local values are calculated using the best possible data, extrapolating these values to all wetland resources on the planet creates problem not least because there is wide variation in the types of wetlands and their component products. Heimlich et al.^[17] presented the results of over 30 studies carried out on wetlands. After accounting for geographical variation and other differences across the studies by calculating the value over a 50-year period discounted at 6% for all the studies and then converting these values to an annual basis, they find significant variation among the different studies. For example, general recreational values ranged from U.S.\$105 to U.S.\$9859 per acre; waterfowl hunting from U.S.\$108 to U.S.\$3101 per acre; and recreational fishing from U.S.\$95 to U.S.\$28,845 per acre.

Table 1 gives a few examples of various studies and types of goods or services valued. As the figures show, there is a wide variation among the types of wetlands valued and the values attributable to them. Great caution must, therefore, be exercised when extrapolating localized studies to other geographical areas. Resource values are influenced by local consumptive and productive use patterns, market conditions, and the institutional arrangements affecting the

use of the resources. The good news is that there are hundreds of studies of wetland values (see the work by Brander et al.^[18] and Marsden Jacob Associates^[19] for an extensive review) that we can refer to for some guidance on the range of values associated with wetlands.

CONCLUSION

Benefits of some wetlands will always be difficult to quantify and measure primarily because the required scientific, technical, or economic data are difficult to obtain and also that certain intrinsic values are not measurable by existing economic valuation methods. However, as the studies reported in this entry suggest, various wetland goods and services are extremely valuable, and in many cases, a measurable economic value can be obtained. The economic value of ecological functions in sustaining the livelihood and cultures of human societies clearly cannot be disregarded in development and conservation policy because these values allow us to make informed decisions about tradeoffs and help in the conservation of natural resources to enhance human welfare. Hence, valuation studies need to be carried out wherever possible and with collaboration between economists and natural scientists to fully capture the economic and ecological linkages that make wetlands valuable.

Wetlands: Gaseous Emissions

S.K. Nag

Fishery Resource and Environmental Management Division, Central Inland Fisheries Research Institute, Barrackpore, Indian Council of Agricultural Research (ICAR), Kolkata, India

Abstract

Wetlands are one of the very important ecosystems known for their ability to act as a carbon (C) sink. Nearly one-third of the total storage of C in earth's soil is stored in wetlands and they play a vital role in global C-cycle. However, wetlands are also a potential source of greenhouse gas (GHG) emission, particularly methane (CH₄). About 20–25% of global CH₄ emission is contributed by wetlands. CH₄ emission from wetlands is dependent on several abiotic and biotic factors like temperature, moisture, water level, redox potential, type of wetland, C-content, presence or absence of vegetation, type of vegetation, comparative ratios of methanogenic and methanotrophic bacteria, etc. Emission of carbon dioxide (CO₂) from wetlands depends on the nature of wetlands and their management practices. There are more production and emission of CO₂ due to aerobic decomposition of organic matter favored by seasonal drying of wetlands as a result of less rainfall, prolonged draught, and harvesting of peat. Wetlands are, however, not a significant source of nitrous oxide (N₂O), the most potent GHG having 310 times more global warming potential than CO₂. But, if moisture level in the wetlands drops significantly when they resemble upland soil and also if water dries up in seasonal wetlands or is drained off in managed systems, there may be more emission of N₂O than usual.

INTRODUCTION

Wetlands are areas of marsh, fen, peatland, or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish, or salty, including areas of marine waters, the depth of which at low tide does not exceed 6 m.^[1] They are actually the interface of aquatic and terrestrial environments and most important natural resource and ecosystems on earth. The extent of wetlands ranges from 7 to 10 million km² or about 5–8% of the land surface of the earth, distributed in all climatic zones ranging from the tropics to the tundra. There are different types of wetlands like peatlands (bog and fen), marsh, swamp, etc.

Although wetlands cover 5–8% of earth's land area, they account for almost one-third of total terrestrial carbon (C) stock^[2,3] and thus play an important role in global C-cycle. They have large potential for sequestering C in their soils because of a positive balance due to a high primary productivity and a less rate of decomposition. But at the same time wetlands can also act as source of greenhouse gas (GHG). Thus, the balance of C uptake and emissions determines whether a wetland is a source or sink of C.

GLOBAL WARMING AND GHGS

Global warming, as is evident from increase in mean annual temperature over the last few decades at the rate of 0.15°C per decade since 1975,^[4,5] is the result of

increased atmospheric concentration of GHGs—three of the most important being carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O). Atmospheric concentration of CO₂ has increased by around 43% from 270–280 ppm in late 1700s to around 400 ppm in 2014.^[6] CH₄ concentration increased 2.5 times from 722 ppb during preindustrial times to 1,800 ppb in 2011.^[4] Since the late 1990s, its concentration in the troposphere is increasing at the rate of 1.1% per year, which is a serious concern.^[7] The concentration of N₂O increased by 16% from 270 ppb at pre-1750 to the level of 325 ppb.^[8] These gases absorb infrared radiation that may lead to increase in mean surface temperature and potential change in climate. About 70% of the world GHG emission comprises of CO₂, followed by CH₄ (20%), N₂O (8%), and other gases (3%). Although CH₄ and N₂O are present at lower concentration in the atmosphere but their global warming potential (GWP) is 21 times higher for CH₄ and 310 for N₂O than that of CO₂.

WETLANDS AND GHG EMISSION

Wetlands are the world's largest natural source of CH₄^[9] and also a source of N₂O but are a potentially important sink of atmospheric CO₂.^[10] Wetlands contribute about 20–25% of the global CH₄ emissions. When submerged rice fields are included in the wetlands definition, then together they are estimated to emit 33–37% of global CH₄.^[11,12] Wetlands are the largest natural CH₄ source,

whereas ruminants, paddy rice cultivation, and fossil fuel use are the largest anthropogenic sources.

Wetlands are also a source of CO₂ when decomposition of organic matter (OM) exceeds production. In addition, seasonal wetlands and those which are sometimes drained for agricultural and other purposes in many parts of the world become a significant source of atmospheric CO₂.^[13]

N₂O, the most potent GHG, results from denitrification that is generated in waterlogged soils by the availability of C and nitrogen (N). Wetlands receiving excessive amounts of nitrates as a result of anthropogenic activities have increased the rate of denitrification and, therefore, may be significant source of N₂O to the atmosphere.

The gaseous C budget of a wetland depends on the CO₂ uptake during photosynthesis and the amount of C lost as either CO₂ from plant and soil respiration or CH₄ emitted by methanogenesis.^[14–16]

Gas fluxes to and from the atmosphere in wetlands can occur via three pathways: the gas-filled tissue or aerenchyma of emergent vegetation, bubbles rising from the substrate to the water surface (ebullition), and hydrodynamic transport of dissolved gas through the surface water.

PRODUCTION OF CH₄ IN WETLANDS

Wetlands contribute 109–145 Tg CH₄ yr⁻¹, i.e., 20–26% of global CH₄ emission (550 Tg CH₄ yr⁻¹) with boreal and tropical wetlands contributing the most.^[2,17] However, the estimates suggest that wetlands may contribute about 180 Tg CH₄ yr⁻¹ 76% of which comes from tropical wetlands.^[18,19] Submerged rice fields, which are also sometimes included in the wetlands, emit about 60–80 Tg CH₄ yr⁻¹ (1 Tg = 10¹² g).

The most comprehensive assessment of global sources of atmospheric CH₄ and their dynamics conducted by Intergovernmental Panel on Climate Change suggests that natural wetlands are responsible for approximately 21% of global CH₄ emissions.

Because of its high GWP, estimation of CH₄ from different sources is one of the urgent tasks in addressing the problem of climate change. Being a major emission source of CH₄, precise estimation of its emission requires credible assessment of wetlands in global or continental scale.

CH₄ is produced in wetlands when labile fraction of OM undergoes mineralization under anaerobic condition by microorganisms called Archaea. CH₄-producing bacteria or methanogens use low-molecular-weight compounds like acetate coming from anaerobic fermentation of OM and ferment them into CH₄ which is the end product of anaerobic decomposition of soil OM.

Alternatively CH₄ is produced from reduction of CO₂.

Methanogenesis requires strictly anaerobic and extremely reduced condition, i.e., redox potential below -200 mV. The presence of other electron (e)-acceptors like NO₃⁻, Fe³⁺, and SO₄²⁻ can inhibit CH₄ production.^[20]

Emission of CH₄ from wetlands to the atmosphere does not depend only on CH₄ production but also on its oxidation which takes place in the upper oxidized soil layer. During convective flow or diffusive transport of CH₄, produced in the lower anaerobic and highly reduced horizon, to the upper layer, the gas comes across with obligate aerobic methanotrophic bacteria present in aerobic soil layer which use molecular oxygen to oxidize CH₄ to CO₂. Thus, emission of CH₄ to the atmosphere is limited.^[12,20] Methanotrophs are estimated to consume about 30 Tg CH₄ yr⁻¹,^[12] an amount close to net annual increase in atmospheric CH₄.^[21]

DRIVERS OF CH₄ PRODUCTION FROM WETLANDS

A large number of physical and biological controlling factors have been identified that are responsible for the huge spatial and temporal variation in CH₄ fluxes from the soil into the atmosphere. CH₄ production, its oxidation, and ultimate emission from wetlands are controlled by several biological, chemical, and physical factors like temperature, moisture, water level, redox potential, time of the day, wetland types, C-content, vegetation, etc.

Temperature

Soil temperature is an important factor, either alone or in combination with other environmental factors, and affects CH₄ flux.^[22] A positive correlation exists between soil temperature and CH₄ emission in temperate freshwater wetlands.^[23–26] In their study on seasonal dynamics of CH₄ flux from natural and constructed wetlands, Singh et al.^[7] observed maximum CH₄ flux during summer season followed by that in rainy and winter seasons which is attributable to a positive correlation with temperature as higher temperature exists in the summer followed by that in rainy and winter seasons. Based on the difference in summer and winter temperatures, Singh et al. reported a Q10 value of 3 which is close to Q10 value of 2.5–3.5 for CH₄ production obtained by others.

Moisture and Water Level

Both the water table height and the soil temperature that influence production and oxidation rates have routinely been identified as main drivers of the CH₄ flux in field studies for more than 20 years. Soil moisture and water levels influence CH₄ flux. Many studies have shown that soil water content is one of the most important factors

influencing GHG fluxes because of its direct effect on microbial activity.^[27,28]

Redox Potential

The oxidation–reduction potential of wetlands is an important factor in determining the GHG emission. Submerged soils are characterized as lacking sufficient oxygen to act as e-acceptor for microbial respirations. A redox potential of –150 mv is essential to methanogenesis by archaeal bacteria.

Diurnal Variation

CH₄ emissions from wetlands vary significantly not only on a seasonal basis but also diurnally.^[29] Ding and Cai^[30] observed that CH₄ emission from freshwater marshes and swamps varied greatly at different times of the day showing increasing rate during the morning reaching a peak in the afternoon and then decreasing in the evening. This diurnal variation becomes more important when plants are growing in the wetland^[31] and the ability of the plant species to transport gas increases.^[32]

The diurnal variation in CH₄ flux in *Carex*-dominated wetland is related to soil temperature variation. Hirota et al.^[31] did not observe any clear relationship between daily CH₄ flux and soil temperature in three emergent plant-dominated zones (*Hippuris* dominated, *Scirpus* dominated, and *Carex* dominated) and one submerged plant

(*Potamogeton*) dominated. In many studies, the relationship between temperature and CH₄ flux from wetlands is reported to be complex ranging from linear, log-linear, or exponential to no correlation.^[33]

Type of Wetland

Most of the CH₄ emission studies have been conducted in peatlands (i.e., bogs, fens, and freshwater marshes). Deep ponds have higher CH₄ flux rates than other types of boreal wetlands. In case of bogs and fens, neutral fens emit more CH₄ than acid fens and bogs. Mangrove wetlands and coastal salt marshes are less emitter than freshwater swamps^[19] which might be due to the fact that salinity inhibits methanogenesis to some extent. Variation in CH₄ emission from diverse types of tropical and subtropical wetlands is depicted in Table 1.

Availability of Organic C

Since the substrate for methanogenesis is organic C compounds in the soil that come from photosynthesis via root exudation, root turnover, and litter production, net ecosystem production is the master variable for the control of CH₄ emissions from wetlands. CH₄ production rates are linearly correlated with water soluble C in the soil or with readily mineralizable C in both field and laboratory conditions. Higher CH₄ emission rates are

Table 1 Examples of rates of GHG flux from different wetlands.

observed from wetlands having higher organic C in the sediment.^[7]

Effect of Vegetation and Plant Species on CH₄ Dynamics

Vegetation is one of the most important drivers of CH₄ dynamics in wetland systems. The mere presence or absence of vegetation as a gas-channel heavily impacts the magnitude of CH₄ flux from sediments to the atmosphere. CH₄ emission from the vegetated surface is many times higher than that from the unvegetated surface of the same water body.^[7] Removal of sedges from arctic wetland can reduce CH₄ emissions and increase accumulation of CH₄ in flooded soils. Sedges provided the main transport pathway for CH₄ release into the atmosphere. Over 85% of net CH₄ emissions from the *Scirpus* and *Phragmites* wetland can be a result of CH₄ releasing to the atmosphere through the root-shoot system.^[42]

CH₄ dynamics varies across plant species growing in the wetlands and their growth characteristics. Presence of some species causes more emission of CH₄ than others even within the same plant families, and for some plants within that family, there may be no detectable emission.^[43] In general, CH₄ emission decreases with increase in plant biomass.

Microbial community analysis of rice rhizospheres indicates high enrichment of a diverse pool of methanogenic archaeal populations.^[44] Rhizosphere acetate levels can differ greatly among plant species and is considered an important precursor to CH₄ production.^[45] Plants in anoxic soil environments significantly alter net CH₄ emissions by increasing its diffusion or flow from flooded sediments via physical traits.^[42]

Effect of Elevated Level of CO₂

CH₄ emissions from wetlands increase in response to higher concentration of CO₂ in the atmosphere.^[46,47] The possible reason for this relation between the two GHGs may be due to increased exudation of plant-derived C in the presence of increased CO₂ or it may be a result of other plant traits that influence net CH₄ production. Plants stimulated by CO₂ fertilization can increase primary production, resulting in higher exudation of organic C.^[46,48] The increase in root-derived C, in turn, directly stimulates the activity and growth of acetoclastic methanogens which produce CH₄.^[49]

Most of the plant physical traits which are affected by elevated CO₂ also impact CH₄ flux. Therefore, changes in the parameters that allow for greater diffusion and flow of CH₄ from soil, through the plant, and into the atmosphere, can increase net CH₄ emissions. Increase in biomass under elevated CO₂ may raise emissions of CH₄ by increasing the rate or volume of CH₄ ventilated through the plant, while greater root biomass could allow more diffusion of

dissolved CH₄ into the roots and aerenchyma where CH₄ ventilation proceeds.^[46]

The development of aerenchyma tissues of aquatic plants provides conduits for CH₄ and supplies their roots with oxygen for CH₄ consumption. Methanogens belong to the domain Archaea, which requires strict anaerobiosis and low redox potentials. However, soil-plant systems also can oxidize a large fraction of the CH₄ produced by methanotrophs inhabiting the root zone.

N₂O Emission

N₂O is an important GHG with an irradiative forcing effect of 310 times that of CO₂ and a life time in the troposphere of approximately 120 yr. Part of N₂O is converted to NO in the stratosphere and so contributes to depletion of ozone. Emission of NO and N₂O is the result of microbial nitrification and denitrification in soils. Nitrification is the main source of N₂O emission under aerobic condition and denitrification under anaerobic condition. Both nitrification and denitrification processes in soil can occur simultaneously and the production of N₂O depends on the balance between these two microbial processes.^[50]

Nitrification

Denitrification

About 55% of global N₂O is emitted from natural ecosystem.^[51] Ocean, estuaries, and rivers account for 5.4 Tg N yr⁻¹ out of estimated emission of around 12.1 Tg N yr⁻¹ from all natural sources. Wetlands are not an important source of N₂O emission unless water levels in these systems drop significantly in which case they behave as upland soil and may emit more N₂O.^[52]

In continuously submerged wetlands under sufficiently reducing condition and available organic substrates, rates of nitrification and subsequent denitrification can be substantial but the denitrification proceeds toward N₂ as the end product and little N₂O is produced en route. But if the wetland is seasonal (i.e., water dries up or drained off in managed systems), there may be more N₂O emission due to increase in the availability of oxygen.

Major environmental factors controlling the N₂O emission are soil organic carbon (SOC) content, vegetation type, soil pH, soil temperature, water content, and soil N particularly NO₃⁻, nitrite, and ammonia. Emission of N₂O

increases with increase in SOC. As soil pH increases and bulk density decreases, N₂O emission decreases. The presence of vegetation also affects the emission of N₂O from wetlands just like CH₄ emission. Without inundation, however, N₂O flux is similar in both the wetlands, vegetated and without vegetation.^[53]

CONCLUSION

Wetlands are among the most unique natural resources on the earth providing a wide array of ecosystem services and are a C sink over long term and thus partly offsetting anthropogenic emissions. But there are uncertainties in the global wetland area, the amount of C stored in their soils as well as the quantity of GHG flux from the wetlands. Few data on rates of GHG flux from different wetlands across the world are given in Table 1.

Most of the studies on GHG emission from wetlands have been conducted in temperate regions which are different in characteristics, climatic, and environmental conditions compared to wetlands in the tropics. Also, there is a lack of estimates of N₂O and CH₄ fluxes from subtropical and tropical climates. Although models developed for prediction of emission of GHGs (e.g., CH₄ and N₂O) work with reasonable accuracy at the site or system for which they were developed, their potential for application in other systems with different management practices has not been widely validated.

Climate change impacts the GHG emission. Rising sea level and ingress of sea water increase the salinity of water in the wetlands of coastal and estuarine belts and reduce CH₄ emission. Similarly changes in land use and the area under wetland or changes in the management practices (like intermittent drying or wetting) affect the volume of GHG emission and the relative proportion of CO₂ and CH₄ produced and emitted from wetlands.

ACKNOWLEDGMENT

The author is highly thankful to Dr. Rattan Lal, Distinguished Professor, The Carbon Management and Sequestration Center, School of Environment and Natural Resources, The Ohio State University, Columbus, Ohio, U.S.A. for providing valuable guidance in the development of manuscript.

Climate Impacts Group, Department of Ecology, Lund University, Lund, Sweden

Abstract

Methane (CH₄) is a trace gas that plays an important role in atmospheric chemistry and the energy balance of the earth. Because of the substantial contribution from natural wetlands, knowledge about the dynamics leading to CH₄ formation and emission is of great importance to understand how these ecosystems interact with the climate and how they would respond to climate change.

INTRODUCTION

Methane (CH₄) is a radiatively active trace gas that plays an important role in atmospheric chemistry and the energy balance of the earth. Its contribution to the greenhouse effect is about 22%, which can be compared to carbon dioxide (CO₂) which contributes approximately 65% to the climate forcing of all long-lived greenhouse gases (excluding water vapor).^[1] In addition to the direct warming effects, where infrared radiation is absorbed and returned to the earth's surface, chemical and photochemical reactions with CH₄ in the troposphere and stratosphere indirectly cause greenhouse warming. The preindustrial atmospheric concentration of CH₄ was about 0.75 ppmv (parts per million by volume), and since then it has more than doubled to approximately 1.73 ppmv.^[1] Anthropogenic sources of CH₄ include cattle (about 15% of the annual CH₄ release), rice paddies (20%), coal mining and oil production (14%), biomass burning (10%), natural gas leaks, and landfills and sewage disposal, while the major natural sources include wetlands (20–25%) and termites (5%).^[2] Because of the substantial contribution from natural wetlands, knowledge about the dynamics leading to CH₄ formation and emission is of great importance to understand how these ecosystems interact with the climate and how they would respond to climate change.

CH₄ PRODUCTION AND CONSUMPTION

CH₄ is produced by strictly anaerobic archaeobacteria that are limited to the use of only a few simple substrates for biosynthesis and energy production.^[3] If available carbon compounds are not directly supplied, they depend on other groups of microorganisms for the initial breakdown of more complex organic structures into simpler molecules.

The reduction of CO₂ with hydrogen is a common pathway to CH₄ formation, but acetate and formate are also important precursors of CH₄ in natural environments. Growth of methanogenic bacteria further requires a very low redox potential (E_h below -400 mV), and the ideal environmental conditions are often met in permanently waterlogged wetlands. However, CH₄ efflux from wetlands to the atmosphere depends not only on the rate of production (methanogenesis) but also on the extent of CH₄ consumption (methanotroph) that may occur in oxic surface layers and in the close vicinity of plant roots.^[4–6] In this process, CH₄ is oxidized to CO₂, and the rate of CH₄ emission that can be measured at the surface is hence the net result of two counteracting processes—methanogenesis and methanotroph.

ENVIRONMENTAL CONTROLS ON CH₄ EMISSIONS

Water Table Position

Water table position in relation to the surface is considered to be the most important factor controlling CH₄ flux because it indicates the boundary between anaerobic CH₄ production and aerobic CH₄ consumption (Fig. 1). Negative correlations between water table depth and rates of CH₄ emission have frequently been reported.^[7–9] It has also been found that the lowering of the water table may result in increased CH₄ emissions when episodic releases of CH₄ trapped in pore water occur and the diffusivity of gases in air-filled pore spaces increases.^[10,11] Field experiments in peat-forming wetlands reveal a high spatial variability of CH₄ emissions caused by distinct micro-topographical features on the wetland surface.^[12] Interactions between vascular plants and mosses create differences in elevation and therefore distance

Fig. 1 The depth of the water table is important in determining net CH_4 emissions from natural wetlands because it indicates the boundary between anaerobic CH_4 production and aerobic CH_4 consumption. CH_4 may be transported from the soil to the atmosphere via diffusion through the soil profile, by bubble ebullition, or by plant-mediated transport. In the first case, CH_4 is subjected to methanotrophic oxidation as it passes through the oxic surface layer, and this acts to decrease net CH_4 emissions. Bubbles are quite stable, meaning that little oxidation takes place, and the same is also true when CH_4 is transported through vascular plants. Vascular plants are sources of methanogenic substrate because they release labile carbon compounds into the soil via root exudation and root turnover. Leakage of O_2 from roots may lead to the inhibition of methanogenesis and methanotrophic CH_4 consumption in the otherwise anoxic soil.

to the water table within a radius of less than a meter.^[13] Scaling up of spot CH_4 emission measurements to larger areas without careful consideration of experimental plot location may therefore be misleading. Laboratory incubations have shown that there is a potential for CH_4 production both above and below the water table,^[14] but the actual production in the field peaks at approximately 5–15 cm below the water table.^[8] For methanotrophic CH_4 consumption to occur, a simultaneous supply of both CH_4 and oxygen is necessary. The abundance and activity of methanotrophic bacteria are therefore highest at the interface between anoxic and oxic conditions, i.e., at the depth of the water table.^[5,14] Watson et al.^[5] used a model to show a high capacity for CH_4 oxidation in peat, where methanotroph accounted for 85% of the oxygen uptake potential when both oxygen and CH_4 were present in excess. In the absence of CH_4 , maximum oxygen uptake potential was near the surface.

Soil Temperature

Correlations between soil temperature and CH_4 production and emission have been found at scales ranging from

laboratory incubations and monolith experiments^[8,11,15] to field investigations at the plot^[16] and landscape scale.^[9]

There is a direct effect of temperature on the metabolic rate of CH_4 -producing microorganisms, but the sensitivity to temperature change is different for methanogens and methanotrophs.^[11,17] In a study carried out with peat slurries under laboratory conditions, Dunfield et al.^[17] found that CH_4 production in peat samples from temperate and subarctic areas was more sensitive to changes in temperature as compared to CH_4 consumption in the same samples. Increasing or decreasing temperatures also interact with other parameters with potential to control CH_4 production and emission to the atmosphere. One such interactive effect would be the relationship between temperature and water table position, where increasing temperatures lead to enhanced evaporation and plant transpiration, with lowering of the water table as a consequence.^[18] It has also been suggested that the temperature dependence of CH_4 production is constrained by substrate limitation and that temperature has an effect on methanogenesis mainly via its influence on substrate availability.^[19] In peat samples from a Swedish acid mire, CH_4 production was stimulated by

increased temperatures only when substrate (glucose) concentrations were simultaneously increased.^[15] It has further been found that the decomposition of labile material is more strongly controlled by temperature than the decomposition of more recalcitrant components.^[18] From the same study, it was also concluded that substrate availability lagged behind rapid temperature changes and that the thermal/hydrological history of the soil was important to determine the rate of CH₄ production.

CH₄ Transport: Diffusion, Bubble Ebullition, and Transport through Plants

The solubility of CH₄ in water is low, and it escapes through waterlogged soil to the atmosphere by diffusion, by bubble ebullition, or by transport through vascular plants (Fig. 1). The rate of CH₄ emission is largely controlled by the mode of transport because the different transportation pathways are associated with more or less extensive CH₄ consumption in the soil profile. CH₄ diffusing through oxic environments is subjected to methanotrophic oxidation to CO₂, and a water table depth of only a few centimeters may cause considerable reductions of CH₄ emissions to the atmosphere. Bubbles form when the rate of CH₄ production causes the sum of the partial pressures of dissolved gases to exceed the value of the hydrostatic pressure in the soil. However, the concentration of CH₄ in bubbles will be at equilibrium with dissolved pore water CH₄. At low rates of methanogenesis and with no vascular plants present, the main release of CH₄ to the atmosphere is likely to be by diffusion, but bubbles begin to form when the production rate exceeds the capacity for diffusive loss.^[20] Once formed, bubbles are quite stable, meaning that little methanotrophic CH₄ oxidation occurs even as they pass through oxic environments. Studies conducted in rice paddies have shown that bubble formation tends to decrease as the plants mature because the progressively better developed rooting system acts as gas conduits and efficiently transports gases out of the soil.^[21] However, a close relationship between vascular plant production and the availability of methanogenic substrate (discussed in the next section) may also speed up the rate of methanogenesis to such an extent that bubble formation is promoted. In order to supply oxygen for respiration to submerged structures, certain vascular plant species develop lacunae in stems, roots, and rhizomes.^[22]

Depending on the species, the ventilation of growing roots is carried out either by pressurized bulk flow or by simple diffusion that follows concentration gradients between the atmosphere and the soil. Leakage of oxygen may give rise to CH₄ oxidation and inhibition of methanogenesis in the close vicinity of the roots.^[5,6] However, net CH₄ emission is generally enhanced by the presence of vascular plants with a deep rooting system because of a “chimney effect,” where CH₄ transported from the soil to the atmosphere within plant lacunae is withdrawn from consumption in oxic conditions.^[12,23,24]

Vascular Plants and Substrate for CH₄ Production

Vascular plants are sources of substrates for CH₄ production because they easily release degradable carbon compounds into the soil via root exudation and root turnover (Fig. 1).^[20,24,25] In peat-forming wetlands, the organic matter becomes increasingly recalcitrant with depth,^[26] and several studies have pointed out that plant-derived inputs of labile carbon compounds could significantly contribute to increased CH₄ production.^[20,23,27] This “loading” of substrates into the soil may further be correlated to the photosynthetic rate of the vascular plants in the ecosystem^[24,28] because the amount of carbon allocated to belowground plant structures and eventually released to the soil is likely proportional to the CO₂ fixation rate.^[24] The overall primary productivity in the ecosystem may therefore be of great importance for the CH₄ emission rates from a wetland area.

Abstract

Wetlands are intimately tied to soils through sedimentation processes. The accretion of sediments accelerates the aging of wetlands, reduces infiltration through bottom substrates increasing water heights, and removes phosphorous, a limiting nutrient in many freshwater ecosystems. In this entry, the mechanics of sedimentation are discussed in relation to natural and constructed wetlands, and ecological engineering principles are suggested as a way to mitigate the effects of excessive sedimentation.

INTRODUCTION

Wetlands are highly efficient at storing and transforming chemicals. The primary input of these chemicals is from overland flow. The characteristics of these chemicals are dependent on the sources in the watershed. The rate of input to riparian zones, however, is dependent on landscape features, such as slope and surface resistance and soil properties, including grain size and cohesive strength. For large flows and loose soils, a significant portion of these chemical inputs can be a result of sediment transport.

PROBLEMS OF SEDIMENTATION IN WETLANDS

Sediment Accretion

The accretion of particulate material in wetlands limits the lifetime of these systems, advancing their succession to a terrestrial ecosystem as a function of sedimentation rates. Three sources of particulate material can be identified as follows: suspended particles derived from the inflow, the production of microbial particles in the wetland, and the production of detritus from macrovegetation. The latter two increase with increased primary production in wetlands. The former is a function of hydraulic loading, defined as the flow, Q , per unit area of wetland, A , i.e., QA^{-1} . Natural wetlands are prominent components of riparian ecosystems that exist either as floodplains, receiving periodic submer-sion, or as part of the riparian corridor, receiving continuous, though varying, inflow. In both cases, flow transports suspended sediments to wetlands. Suspended material is often deposited as current velocities decrease in broad, shallow expanses of wetlands. Sediment transport is a

function of total flow (and thus rainfall intensity) in a watershed and also depends on the slope of the landscape and the susceptibility of soils to erosion. Steep slopes with highly unconsolidated soils will contribute to large suspended sediment loads during high runoff events. For low-flow events, suspended sediment concentrations do not exceed 20 mg/L while for high flows they can exceed 80 mg/L.^[1] In extreme cases of accretion, sedimentation rates of 26.67 cm/yr can bury emergent grasses because sediment accumulation outpaces plant growth.^[2] In contrast, constructed wetlands are designed to treat wastewater having steady and high suspended solid concentrations, ranging from 20 to 75 mg/L, and volumetric ratios of settleable solids from 5 to 20 ml/L.^[3]

Reduced Conductivity of the Bed

Wetlands can experience reduced infiltration rates as particulate matter clogs bottom substrates. Generally, a reduction of hydraulic conductivity occurs with increasing hydraulic loading to the wetland. As a consequence of lower current velocities and higher sedimentation rates with increasing distance from the inlet, the hydraulic conductivity is lowest near the inlet and highest near the outlet. A general design criterion for wetlands is a hydraulic conductivity 1500 m/day based on the bed of 1.25–2.5 cm diameter gravel.^[4]

Phosphorus (P) Accumulation

The accretion of organic material on the bed results in wetlands with a high ion exchange capacity. The beds are partially responsible for the removal of phosphates by

sorption until they become saturated. The movement of P through the bed is slower than the hydraulic conductivity as a result of the storage (exchange) capacity of the bed.^[5] Plant uptake of phosphates is limited because a reduced hydraulic conductivity decreases infiltration and thus transport of phosphates to plant roots.^[6] A more consistent process for phosphate removal is by adsorption onto suspended sediments and their subsequent deposition.^[7] P loading is directly proportional to suspended sediment concentrations and hydraulic loading. It is estimated that 40 mg P accompanies each gram of suspended solids entering wetlands.^[1] Higher loading rates occur for flows over landscapes rich in P, such as agricultural lands. During periods of inundation, wetlands are characterized by aerobic and anaerobic soil zones. In anaerobic zones, the decreased redox potential leads to an increase in the solubility of particulate P, which may be discharged from the wetlands. This dynamic feedback between removal of P by sedimentation and release of P after particulate accretion often leads to the variable retention of P by wetlands. Despite the mineralization of particulate P, wetlands are generally sinks for P, with removal as high as 97%.^[8] The retention of P, however, decreases as P loading increases^[9] and often decreases through the life of the wetland.^[10]

PARTICLE TYPES AND SEDIMENTATION PROCESSES IN WETLANDS

The size distribution of particles in a wetland varies from nanometer-sized colloidal material through micrometer phytoplankton and heterotrophic organisms to millimeter- and centimeter-sized leaf detritus and sediments. For discrete particles, settling results from the force balance between particle weight (F_w) and drag on the particle such that:

$$F_w = F_D = \rho C_D A_{pr} \frac{w^2}{2} = (\rho_p - \rho) V g \quad (1)$$

where C_D is the drag coefficient on a 2-D surface, A_{pr} is the projected area of the particle, w is the settling speed, ρ_p and ρ are the particle and water densities, respectively, V is the volume of the particle, and g is the gravitational acceleration (9.8 m/sec²). Solving for settling rate, w , gives:

$$w = \sqrt{2 \frac{(\rho_p - \rho) V g}{\rho A_{pr} C_D}} \quad (2)$$

Thus, the settling rate of a particle is proportional to the excess density of the particles over that of water and the length scale of the particle defined by VA_{pr}^{-1} . Providing flow is not turbulent, specified as a Reynolds number $Re < 0.1$, and particle shape is unimportant to the drag; C_D can be approximated as follows:

$$C_D = \frac{24}{Re} = \frac{24v}{2Rw} \quad (3)$$

where R is the radius of the particle. Assuming a spherical particle, the above equation reduces to:

$$w = \frac{2\rho'gR^2}{9v} \quad (4)$$

the celebrated Stokes' Law for sinking particles. Here the excess density is written as follows:

$$\rho' = \frac{\rho_p - \rho}{\rho} \quad (5)$$

For biological material, excess density is less than 0.1%, and size is the determining factor. For this reason, small microbial organisms will sink slower than larger detrital material. The excess density of suspended sediments can reach 260%, indicating that the density is responsible for the high settling rates of suspended sediments.

Sedimentation in a wetland will occur if the settling speed is greater than the surface loading rate per area of wetland, or $w > QA^{-1}$. Given the large spectrum of particle types in natural flows, w is usually calculated based on the size and density of the particle type to be removed. Dividing the depth by the sinking rate gives the retention time in the wetland. Particles that are vertically well mixed as they enter a wetland will have a uniform concentration distribution comprising the spectrum of particle sizes. If the settling rate of the particle, w_p , is greater than w , the particle will be deposited in the wetland cell. For particles with $w_p < w$, the fraction of particles that will be removed is X_p . Thus, the total particle removal by a wetland can be calculated as follows:

$$FR = (1 - X_c) + QA^{-1} \sum X_r \Delta x \quad (6)$$

where $1 - X_c$ is the fraction of particles removed with sinking speeds $w_p > w$ and $QA^{-1} \sum X_r \Delta x$ is the fraction with a settling speed $w_p < w$ that are removed over a distance Δx , along the path of the flow.^[3] The crucial step in determining the sedimentation rate in wetlands is first determining the settling rate of each concentration fraction, either by settling columns or by size-concentration measurements.

Often the aggregations of particles form in wetlands,^[11] a process called flocculation. Sedimentation rates of aggregates are dominated by organic particles of fractal dimension.^[12] Aggregates tend to settle faster than their discrete component particles, and the only way to determine removal rate is by carefully transferring flocs to a settling column and determining the percent removal as a function of the height of the column and time.^[3]

In wetlands with a high concentration of suspended solids, settling is affected by the contact between particles. This would occur in the bottom sediments of most wetlands where two settling processes can be identified: hindered and compression settling.^[3] The hindered zone is marked

by a large gradation in particle concentrations, which is less than the total concentrated in the compression zone. By plotting the concentration of particles over the height of a settling column as a function of time, a break point can be found in the time from hindered settling to compression settling.^[3]

Because large, heavy particles settle out first, the highest sedimentation rates in wetlands are near the inlets. As mentioned above, the hydraulic conductivity through the bottom sediment decreases as clogging occurs. Because clogging is also a function of distance from the inlet, the most accurate estimate of the hydraulic conductivity is to measure the change in water surface elevation with increasing distance from the inlet. However, as Kadlec and Watson^[11] show, this is not a simple function of Darcy's Law but must include evapotranspiration in the wetland. For newly constructed wetlands, the hydraulic conductivity of the bottom substrate (gravel, sand, and mud) cannot be used because clogging will result from sediment accretion.^[4]

ECOLOGICAL ENGINEERING SOLUTIONS TO SEDIMENTATION

To keep suspended particles entrained by flows from accruing in wetlands and clogging bottom sediments, one or more settling basins can be included between the inlet channel and the wetland cell. This would have the following two effects: first, to collect all but the finest and least dense suspended particles and, second, to remove P from the inflow.

To overcome the problem of detrital accumulation in wetlands, woody plants could be substituted for grasses and periodically harvested. This would not only reduce the amount of biomass accrued in the wetland but also increase the efficiency of nutrient uptake in the unclogged root zone and provide a potentially marketable resource. Because phytoplankton are the most abundant nutrient filters in a wetland and have intrinsically low sinking rates, a wetland could be designed with the low retention of suspended plankton to further reduce sedimentation while improving nutrient removal. A settling basin could then be sized to accumulate these nutrient-rich particles for harvesting before nutrients are remineralized. To keep flocs of particles from forming in wetlands, cells could be mixed with aerators or inlet pumps. This would break up flocs, which would be exported as discrete particles.

CONCLUSION

Because wetlands are always shallow to promote macrophyte growth, they essentially act as flat plate collectors of

sinking particles. The dominant particles in wetlands are suspended particles in the inflow and biomass of vegetation resulting from growth in the wetlands. The processes of sedimentation can reduce a wetland's storage capacity, its efficiency to retain nutrients, and its lifetime. Future efforts should be aimed at enhancing nutrient removal while reducing sedimentation. This can be done with engineered structures, such as settling basins and grit chambers, or by less costly technologies such as stilling wells. More innovative green solutions are on the horizon.

Wind Erosion: Climate Change

Alan Busacca

Department of Crop and Soil Sciences, Washington State University, Pullman, Washington, U.S.A.

David Chandler

Plant, Soils and Biometeorology Department, Utah State University, Logan, Utah, U.S.A.

Abstract

Wind erosion is a common phenomenon in areas of arid and semiarid climate and sparse vegetation. As much as 30% of the earth's land area is susceptible to wind erosion. Human impacts, such as farming, grazing, deforestation, urbanization, and withdrawal of groundwater, may contribute as much as 20–30% of the total. As human land use encompasses ever greater areas of earth's arid and semiarid lands, the control of wind erosion will increasingly require decision making that accounts fully for climate change and climate variability.

INTRODUCTION

Wind erosion has been driven by cycles of climate change over geologic time, resulting in the transport and accumulation of eolian sediments. As an important process in the Pleistocene Epoch, or Ice Ages, it left conspicuous eolian deposits throughout the world. Wind erosion, driven by shorter timescale changes in climate, has occurred during the interglacial period of the last 12,000 years. This time period has also seen the rise of human societies, the development of agriculture, and, in the last 200 years, the technological age in which human population increased from less than one billion to more than six billion. The methods we use to study climate change and wind erosion shift at the major glacial–interglacial climatic transition that occurred 12,000 years ago. That is, to reconstruct wind erosion events during the Pleistocene Epoch and their causes, such as climate change, we have relied on geologic studies of the deposits resulting from wind erosion. To reconstruct events that occurred 12,000 years ago, however, we have variably detailed archeological and written records of wind erosion and climate change, in addition. In the last several decades, we have added increasingly detailed observations of meteorological and wind-erosion events from global networks of satellites and remote sensors. Since the 1980s, we have added regional- to global-scale computer models to investigate both ancient and modern wind erosion events and their causes.^[1]

Wind erosion is a common phenomenon in areas of arid and semiarid climate and sparse vegetation. As much as 30% of the earth's land area is susceptible to wind erosion. The total annual production of mineral aerosols from wind erosion is estimated as one to two billion metric tons.^[2]

Human impacts, such as farming, grazing, deforestation, urbanization, and withdrawal of groundwater, may contribute as much as 20–30% of the total. Strikingly, during the cold phases or glacials of the Pleistocene Epoch, wind erosion, as judged by reconstructions from dust in polar ice caps and in deep-sea sediments, may have been one order of magnitude or more greater than that of today.^[3]

WIND EROSION AND CLIMATE CHANGE IN THE GEOLOGIC RECORD

Eolian deposits associated with ancient wind erosion events have been identified back to the Proterozoic (600–2500 Ma).^[3] It is especially difficult to reconstruct ancient environments and the paleoclimatic significance of eolian deposits before the Devonian Period (360–410 Ma), when land surfaces were first colonized by plants.^[3]

About 10% of the land area of the earth is covered by Loess (i.e., deposits of windblown silt; [Fig. 1](#)) in several different climatic settings,^[3–5] and perhaps a similar area is covered by sand dunes and sand seas in semiarid and arid climate areas. To a great extent, these are the tangible products of very active wind-erosion processes triggered by global climatic changes beginning in the Pleistocene Epoch and continuing through the interglacial period. Eolian dust, an important component of soils downwind of areas of wind erosion, may play a role in renewing plant nutrients in areas of rapid leaching in the tropics (e.g., the input of Saharan dust to soils of the Amazon basin).^[1] Thus, global pedological and biogeochemical cycles may be affected by climatically induced dust aerosols. Deep-ocean sediments

Fig. 1 The global distribution of major eolian deposits.

Source: From Thomas.^[3]

dating from the last glacial maximum (LGM) in many places contain up to 20% quartz from eolian dust (Fig. 2).^[3,4]

Wind erosion, driven by climate change, has played an important role in human history and development over the last 12,000 years. By some measures of dust aerosols, however, eolian sediment fluxes during the LGM about 18,000 years ago were “10–40 times” higher than during the present day.^[5,6] The principal means by which geologists and paleoclimatologists have reconstructed past episodes of wind erosion and linked them to changing climates has been the stratigraphy, geomorphology, and chronology of eolian deposits associated with arid, semiarid, and periglacial areas. These studies began in the mid-19th century and accelerated with new age-dating techniques after the World War II. Starting in the 1960s, more refined reconstructions of past wind erosion and links to climate change were made possible by examination of eolian materials, mainly dust, in cores from Arctic and Antarctic glacial ice and in deep-sea sediments.^[1,6]

Stratigraphic studies of ice cores, deep-sea sediments, and Loess demonstrate that atmospheric dust deposition changed markedly over glacial to interglacial as well as over shorter timescales. Dust deposition shows millennial-scale variation that tracks the patterns of other

paleoenvironmental indicators, such as atmospheric CO₂ concentrations,^[1] thereby suggesting a direct, but not necessarily simple, link to climate change over several time-scales. Stratigraphic studies confirm that the LGM had much greater wind erosion, with periglacial and peridesert zones of the temperate latitudes and peridesert zones of Africa showing dramatic increases in dust fluxes,^[1,5] while other regions showed decreases in dust flux.

Three causes may explain why wind erosion and dust loading into the atmosphere were higher during glacials than interglacials: increased wind speeds, reduced intensity of the hydrologic cycle, and expansion of eroding areas.^[1] Increased wind speeds would increase the probability of exceeding the threshold velocity for sediment entrainment. Reduced intensity of the hydrologic cycle (less precipitation) could allow dust to remain longer in the atmosphere and be carried farther from the source before rainout would occur. Source areas probably expanded by: 1) exposure of sediments on continental shelves with lowered sea level; 2) deposition of large volumes of outwash from continental and alpine glaciers, especially in the northern hemisphere; and 3) reduction in soil moisture and/or reduction in plant cover. Simulations of the atmosphere during glacial climates show an increase in wind intensities, but direct evidence of higher wind speeds is equivocal.^[1] Some models

Fig. 2 Distribution of weight percent quartz (carbonate free) in Atlantic sediments of the LGM (18,000 years B.P.).

Source: From Pye.^[4]

predict that there were strong cyclonic winds in areas of periglacial outwash in front of major northern hemisphere ice sheets.^[1] Temperature depression at the LGM is estimated to have 10°C or more in temperate latitudes. These estimates are based on pollen evidence for changes in vegetation. Such decreases in temperature would have resulted in decreased intensity of the hydrologic cycle. Evidence regarding lake levels suggests that runoff was less than it is over much of the globe, including the Sahel in northern Africa.^[5] Drier soils and colder temperatures also drove the expansion of desert, grassland, and shrubland at the expense of forests, resulting in a worldwide increase in the area susceptible to wind erosion. Widespread Loess deposits in North America, Europe, Asia, and South America^[4,5] are of glacial age, which also suggests that the LGM was more arid or that sediment production was more robust (e.g., glacial erosion).

Detailed paleoenvironmental studies of Saharan sand seas have produced process-response models of environmental change driven by arid-humid cycles that result from orbital forcing of climate (Fig. 3).^[7] For example, in Fig. 3, the model predicts that during humid phases, sediment production by chemical weathering and alluviation dominates, and eolian systems are stabilized by soil moisture and vegetation. In contrast, during arid phases, transport capacity and sediment availability increase, resulting in time-lagged deflation of sediments accumulated during the humid phase with construction of eolian deposits.^[7]

The deserts and the Loess Plateau in northern China (Fig. 1) form perhaps the most famous example of an eolian system coupled to glacial-interglacial changes in the global climate system. As many as 40 Loess units are interstratified with Paleosols, thereby representing 2.5 million years of record. The cyclical alternation of Loess and Paleosols is thought to represent fluctuations in the dominance of the Asian winter (dust transporting) and summer (precipitation bringing) monsoons associated with variations in earth's orbital parameters that drove the Ice Ages. At the desert margins, sand beds within the Loess suggest that the desert margin advanced many kilometers to the south by active dune migration during cold glacial periods of intensified winter monsoon. Conversely, Loess or Paleosols in desert sites suggest northern movement of the boundary.^[8]

The results of simulation modeling of radiative forcing today and during the LGM are intriguing. They suggest that dust aerosols in the atmosphere from wind erosion, anthropogenic sources, and volcanic eruptions can "effect" climate change as well as "result from" climate change (e.g., the cooling of global temperatures after the eruption of Mount Pinatubo in 1991). The dustiness of the LGM atmosphere could have produced an additional cooling of 3°C beyond predictions, based on orbital forcing, ice-sheet albedo, and CO₂ forcing alone,^[11] although different models produce different latitudinal distributions of predicted temperature change.

WIND EROSION AND CLIMATE CHANGE IN HUMAN HISTORY AND TODAY

"Climate change" refers to statistical changes in climatic variables such as temperature, evaporation, or precipitation over a long period, relative to human records, such as decades to centuries. "Climate variability" refers to statistical changes in climate variables over shorter timescales, such as months to years. In recorded human history, wind erosion has related both to dry periods within the natural cycles of climate variability and to progressive, long-term climate change. Throughout history and around the world, humankind has responded to the agricultural challenge posed by climate variability and climate change by developing hydraulic infrastructure, especially in areas of arid and semiarid climates. The fall of ancient hydraulic systems,

Fig. 3 A climate change driven process-response model based on sediment production, sediment availability (supply), and transport capacity of wind for Saharan sand seas.

Source: From Kocurek.^[7]

such as those in Mesopotamia and along the Indus River, and the subsequent wind erosion, soil degradation, and societal collapse have often been attributed to climate change.^[9] Chinese records document quasi-periodic variations in rainfall, temperature, and dustfall for the past 2000 years, with periods ranging from 2 to 100 years.^[10] Periods of high dustfall were strongly correlated with periods of drought.

When human impacts to the natural and agricultural environment are added to natural climate variability and climate change, greater wind erosion is likely to occur than would be the case under climate change alone. The world's arid and semiarid areas have the greatest interannual variability of rainfall (Fig. 4).^[9] Although ancient sand seas

continue to shift by dune migration, generation of dust aerosols is generally low because deflation has already occurred.^[5] Areas at greatest risk of wind erosion with soil degradation are those at desert margins. The fine- to medium-textured soils deposited previously by deflation at desert margins are often ideal for agriculture but particularly susceptible to entrainment by wind. Human disturbance of eolian soils, such as fallow rotations in dryland agriculture, can lead to accelerated wind erosion, as in the U.S. Great Plains during the Dust Bowl years of the 1930s.

Drought can persist for decades in some arid and semi-arid areas, with dramatic effects on plant cover, soil moisture, and consequent wind erosion. In the Sahel of West Africa, where decadal-scale fluctuations in climate are

Fig. 4 Interannual variability of rainfall on the surface of the earth. Source: From Mainguet^[9] and Nicholson.^[11]

particularly strong,^[12] mean annual rainfall decreased by 25–40% from 1968 to 1997. West Africa is the source of nearly half of the mineral dust in the atmosphere today. Analysis of dust storms over West Africa shows a steady increase in the frequency of dust occurrence since the early 1970s, which parallels negative rainfall anomalies during this period. The source is principally the semiarid Sahel, not the Sahara desert as once was assumed.^[12] Paradoxically, some measurements and models suggest that atmospheric dust over the Sahel has an important climatic feedback effect that may prolong drought cycles by scattering or absorbing solar radiation or even by modifying the African Easterly Jet.^[12] Dust from the Sahel is carried into the upper atmosphere and transported across the Atlantic Ocean to Bermuda, the Caribbean islands, and even the Amazon Basin.^[11]

Redistribution of surface water also can drive local and regional changes in surface hydrology that result in wind erosion. The diversion of the Owens River to Los Angeles, California, in the early 1900s, turned Owens Lake into a 300-km² dry playa, known for wind erosion and dust generation. A agreement to flood parts of the lakebed avoids decades of litigation and sets a goal to meet federal air quality standards. In Central Asia, large-scale river diversions for irrigation led to the desiccation of Lake Aral. The dramatic reduction in the lake's surface area diminished its effect as a regulator of regional climate and exposed over two million hectares of salinized lake bottom sediments. The combined effect of a shorter growing season, degraded soils, higher winds, and exposed sediments results in erosion of millions of tons of dust and salts annually.^[9] For the lands above the rapidly depleting Ogallala Aquifer in southwestern Kansas and the Oklahoma–Texas Panhandle, deep well irrigation has been key to limiting the recurrence of the Dust Bowl.^[13,14]

Individual severe wind erosion events can also be triggered by extreme synoptic weather patterns, with or without antecedent drought. For example, in 1998, on April 15 and 19, two intense dust storms were generated over the Gobi Desert by springtime cold weather systems. The April 15 dust cloud was removed by precipitation over East Asia. The April 19 dust cloud was transported across the Pacific in five days. Part of the dust subsided to the surface between British Columbia and California, producing average Asian dust concentrations over the West Coast of about 20–50 µg/m³. The 1998 Asian dust event was larger than any other similar event in western North America in the 20th century.

WIND EROSION AND CLIMATE CHANGE IN THE FUTURE

There is considerable interest in the prediction of future climate change, especially in light of the increasing rate of global warming over the past several decades. Several

general circulation models (GCMs) have been applied to estimate climate change driven by rising atmospheric CO₂ levels. These models have more been coupled with the effects of atmospheric aerosols such as sulfate and anthropogenic dust.^[11] The best estimate for the year 2100, under a doubled concentration of CO₂ and incorporating aerosols, is a temperature increase of 1.0–3.5°C,^[14,15] with an increase in global average precipitation ranging from 5% to 15%. Paradoxically, the GCMs also predict that mid-continental land areas in the middle latitudes of the northern hemisphere may undergo a drying trend in summer.^[14] This could have the effect of increasing the potential for wind erosion in critical areas, such as the Great Plains of North America and the desert basins of Asia, especially if human land use results in lesser plant or crop cover. Different predictions come from models that take into account the physiological effects of increased CO₂ on plant growth and climatic warming. These models predict substantial reductions in the area of arid and semiarid vegetation and thus reductions of about 20% in source areas for potential wind erosion.^[11]

Under greenhouse warming, changes will occur not only in the mean values of climate variables but also in the frequency and severity of extreme weather events,^[14] owing to the increased energy in the atmosphere. The predicted increase in variability of temperature, rainfall, and wind speed, already high in arid and semiarid areas (Fig. 4), may exacerbate wind erosion of mid-continental agricultural, range, and desert lands. Although smaller changes in mean values of climatic variables are predicted for tropical latitudes, wind erosion could increase in these areas as well.

Under greenhouse warming scenarios, the severity of drought in the Great Plains of North America may well exceed that experienced during the Dust Bowl.^[14] In the mid-latitudes and in other arid and semiarid areas at low latitudes, increased incidence of high-wind events could begin to “pirate” or erode the large deposits of eolian sands and Loess that were emplaced during the LGM, if plant cover is reduced. According to estimates, present wind speeds exceed the threshold wind velocity 30–60% of the time,^[5] thus the eolian soils of the Great Plains are poised for renewed wind erosion if existing plant cover or land use patterns are significantly disturbed. Dropping water tables in the Ogallala aquifer may eventually force the abandonment of up to six million hectares of irrigated cropland on soils sensitive to wind erosion.^[13] A similar situation may occur in the irrigated lands around Lake Aral. The legacies of ancient hydraulic societies, which rose to high levels of achievement but then collapsed upon climate change, raise questions about the future of hydraulic societies.^[14] If the competition for freshwater resources continues to increase and the availability of groundwater resources declines, especially under climate change scenarios, a reduction or relocation of irrigated croplands is possible.

Improved stochastic climate modeling, coupled with proper land use management of the agricultural lands at the desert margins, may provide the means to limit wind erosion of those lands under future climates. As human land use encompasses ever greater areas of earth's arid and semiarid lands in the future, the control of wind erosion will increasingly require decision making that accounts fully for climate change and climate variability.

Wind Erosion: Control Measures

Gary L. Tibke

*U.S. Department of Agriculture—Wind Erosion Research Unit (USDA-WERU),
Kansas State University, Manhattan, Kansas, U.S.A.*

Abstract

Wind erosion can be controlled by maintaining vegetative residues on the soil surface, reducing field width, utilizing stable soil aggregates, roughing of the land surface, and reshaping the land (i.e., the five basic principles of wind erosion control). While individual conservation practices can be successful in controlling erosion, a combination of practices should generally be considered when a wind erosion control system is being planned.

INTRODUCTION

Wind erosion can be controlled by reducing the wind forces at the soil surface or by creating surface conditions more resistant to wind forces.^[1] This can be accomplished by maintaining vegetative residues on the soil surface, reducing field width, utilizing stable soil aggregates, roughing of the land surface, and reshaping the land (i.e., the five basic principles of wind erosion control). While individual conservation practices can be successful in controlling erosion, a combination of practices should generally be considered when a wind erosion control system is being planned. Droughts will cause a shortage of residue in the stubble mulch program, erosive winds will not always blow in the prevailing direction when barriers are used, and soil clods and ridging for erosion control are temporary control measures and best serve as supplemental practices. Conditions conducive to wind erosion exist when the soil surface is loose, dry, and finely granulated, when the soil surface is smooth and vegetative cover is sparse or absent, and when the susceptible area is sufficiently large. Wind erosion control is usually needed in areas with low and variable precipitation and frequent droughts and in areas where high winds, high temperatures, and consequent high evaporation prevail.^[2] Control is also needed in areas where crops that are easily damaged by moving soil particles are grown on highly erodible soils. Research has shown that it is possible to alter some of the components of the erosion process and that this can be accomplished with one or more of the five basic principles of wind erosion control.^[3]

ESTABLISHING AND MAINTAINING VEGETATION OR VEGETATIVE RESIDUES TO PROTECT THE SOIL

On unprotected fallow fields, applying the principle of vegetative cover can best be done by practicing no-till or

stubble mulch farming.^[4] The importance of vegetative protection on the land cannot be overstressed.

Stubble Mulching

Stubble mulching is a form of subsurface conservation tillage, where the soil is tilled without inversion. Tillage tools, such as chisels, field cultivators, sweeps, or blades, are used (Fig. 1).

Weed control is accomplished with cultivation and/or herbicides. The level of protection afforded by stubble mulching is proportional to the kind, quantity, and orientation of crop residue maintained on the soil surface. Excessive use of tillage implements that bury crop residues is the major cause of inadequate vegetative cover for erosion control on cropland. Also, tillage operations that flatten crop residues must be minimized. Standing residues are 5 to 10 times more effective in controlling wind erosion than flat residue. Conservation tillage systems must be designed to avoid excessive loss of surface residues, if effective wind erosion control is to be accomplished.

No-Tillage

Since 1990, no-till farming has grown from 6% to more than 16% of the planted acres in the United States (Fig. 2). This is an increase of over 32 million acres.^[5] No-till is a procedure whereby a crop is planted directly into a seedbed that has not been tilled since harvest of the previous crop. Only the immediate seed zone is disturbed, and no additional tillage occurs. Many studies have shown that a no-till program is a way to virtually eliminate erosion problems (Table 1).^[6]

The bodies of plants and animals that have finished their life cycle are involved in the processes of soil formation and help to generate fertile and productive soils. No-till largely approximates this ingenious work of nature since it in fact makes use of crop residue for this purpose.

Fig. 1 Stubble mulch tillage.
Source: Courtesy of U.S. Department of Agriculture (USDA).

In many farming systems, the plow can be replaced efficiently by biological activities. Plants, roots, worms, arthropods, and other living beings are natural cultivators of the soil. In one study, after 7 years of no-till, the earth worm population was 36 times higher than the population in a conventionally tilled field.^[7] The switch to no-till causes many soil changes. The type and extent of changes depend on soil type, climate, and farming history. Farmers who have no-tilled for some years usually notice more soil moisture, better seedbed tilth, more organic matter and earthworms, less soil erosion, and improved trafficability.^[8]

Cover Crops

The purpose of a cover crop is to produce vegetative protection for the land against wind and water erosion. Cover crops are usually planted when protective residues are inadequate, and winter and spring winds are high. Cover crops

are also planted between rows to provide protection for vegetable or other crops that are highly susceptible to abrasive injury in the seedling stage. Cover crops are best suited to humid and higher rainfall areas or irrigated land. In many of the semiarid and arid areas of the Great Plains and intermountain valleys, cover crops are not practical because they compete for nutrients and limited soil moisture. Generally, cover crops are used in these dry non-irrigated areas only to control erosion on erosion-susceptible knolls or where low residue crops have been grown.

REDUCING FIELD WIDTHS BY ESTABLISHING BARRIERS OR STRIP CROPPING

Windbreaks and wind barriers contribute to wind erosion control by reducing wind speed, on their leeward side, below the threshold required for initiation of soil movement and by decreasing the field length along the erosive wind direction (Fig. 3).

The main effect of reducing downwind field length is a reduction in breakdown of clods and crust by abrasion from saltating (hopping) particles. Abrasion of soil surface components and breakage of saltating aggregates increase the

Fig. 3 Windbreaks and strip cropping.
Source: Courtesy of USDA.

soil flow with distance downwind. This in turn reduces surface roughness and permits even higher rates of soil transport for a given wind speed. The downwind rate of soil movement varies directly with erodibility of the surface and the width of the eroding field. The effect of any barrier in reducing the rate of soil movement depends on the wind velocity and direction, the threshold velocities needed to initiate soil movement and the barrier shape, width, height and porosity. For planning purposes, the distance of 10 barrier heights (h) has been widely adopted as the minimum protected area on the leeward side of barriers.

The rate of soil movement by wind varies directly as the cube of the wind speed (wind erosion force), above the threshold, and inversely with surface soil water. Considering this, it is apparent that a small decrease in wind speed, some distance from the barrier, could still result in a significant decrease in wind erosion forces.^[9] In one test, the wind speed at 12-h leeward of a barrier was 62% of open-field velocity, whereas wind speed cubed (wind erosion force) was only 25% of that in the open field.^[10]

Tree Windbreaks

One advantage of windbreaks over most other types of wind erosion control is their relative permanency. Siddoway and Fenster^[11] made the point that during a series of drought years, windbreaks may be the only effective and persistent control measure on cropland. Single-row plantings are most common in field windbreaks, and 2- to 5-row plantings are used for farmstead and wildlife protection (Fig. 4). Chepil^[12] found single-row field windbreaks more suitable than double or multiple rows because they occupied the least amount of land area for the amount of protection derived from them.

It usually takes many years for tree windbreaks to reach sufficient height and density for good protection, especially in semiarid areas. Therefore, if used, windbreaks require a

Fig. 4 Single-row field windbreak.

combination of other conservation practices if they are to be successful.

Herbaceous Wind Barriers

Herbaceous barriers (annual and perennial) have worked well for controlling wind erosion, trapping snow, and reducing evaporation in dryland cropping areas (Fig. 5).

Additional advantages of perennial grass barriers, as Black and Bauer^[13] explained, are ease of establishment, low cost, and lack of potential injury from herbicides used for broadleaf weed control. Research in Montana by Aase, Siddoway, and Black^[14] on tall wheatgrass (*Thinopyrum ponticum*) barriers showed that the barrier-protected land would only experience 6.6% of open-field erosion for the entire year.

Artificial Barriers

Artificial barriers such as snow fencing, board walls, bamboo (*Bambusa bambos*) and willow (*Salix* spp.) fences, earthen banks, hand-inserted straw rows, and rock walls have been used for wind erosion control but only on a very limited basis. There is usually a very high cost in material and labor to construct these barriers, and their use generally restricted to high-value crops.

Strip Cropping

Strip cropping is dividing a large field into strips that are narrow enough to help control wind erosion. Usually strips of erosion-resistant crops or standing stubble are alternated with other crops or unprotected fallow fields. Strip cropping reduces the ever increasing downwind abrasion caused by wind eroding fields and is a very effective erosion control method used extensively in the northern Great

Fig. 5 Herbaceous wind barriers.

Plains of the United States, Canada, and the spring wheat (*Triticum aestivum*) region of Russia.

MAINTAINING STABLE AGGREGATES OR CLOUDS ON THE SOIL SURFACE

Texture is the dominant soil characteristic relative to inherent erodibility. In general, susceptibility to wind erosion increases as soil texture becomes coarser. Sandy or coarse-textured soil classes lack sufficient amounts of silt and clay to bind sand particles together and form soil aggregates or clods resistant to wind erosion. Consequently, such soils form a “single grain” structure or weakly cemented clods, a condition that is quite susceptible to erosion by wind. A soil surface of stable aggregates of about 70% clods >0.84 mm in diameter resists erosion from all but the highest winds.^[9] Clods of this size are not easily moved by wind, and they protect smaller clods and particles in their lee. Loams, silt loams, and clay loams tend to form the most stable aggregates and are, therefore, the least affected by erosive winds. The type of tillage equipment used has a definite influence on soil cloddiness and surface roughness. Smika and Greb^[15] found that tillage by machines other than the chisel tend to reduce the non-erodible soil aggregation. One-way, offset, or tandem disks leave a smooth surface. Subsurface sweeps, because they do not disturb the soil surface, do not create a rough, ridged soil surface, but they do maintain a greater vegetative roughness by allowing some of the vegetation to remain erect.^[16]

ROUGHENING THE LAND SURFACE

Soil surface roughness is composed of anchored vegetative material, soil ridges, soil clods, or the combinations of all three. All help to control wind erosion by lowering the wind velocity near the soil surface and by sheltering erodible soil fractions.^[17] Tillage implements form ridges and depressions that alter wind velocity. The depressions behind the ridges trap saltating soil particles and stop the normal buildup of eroding material downwind.

Emergency Tillage

Emergency tillage is a last-resort wind erosion control practice that can provide a rough, cloddy surface. It is usually carried out when vegetative cover is depleted by excessive grazing, drought, and improper or excessive tillage, or by growing crops that produce little or no residue (Fig. 6).

Emergency tillage is an inadequate wind erosion control measure, and its only purpose is to create a temporary erosion-resistant soil surface. Implements such as listers, chisels, shovels, and “sand fighters” should traverse fields at right angles to erosive winds to roughen the soil surface and bring clods to the surface.^[9] Listers and narrow chisels were found by Chepil and Woodruff^[16] to have the most

Fig. 6 Field following emergency tillage.

Source: Photo courtesy of USDA.

effective tillage points for emergency tillage. Listers provide a high degree of roughness, and in extremely sandy soils, where clods can be produced only by deep tillage, which are the most effective tools available. Chisel cultivators are more widely used because they require less power and destroy less growing crop than listers.

RESHAPING THE LAND TO REDUCE EROSION ON KNOLLS

Reshaping the land by leveling knolls and benching slopes to shorten the unsheltered distance is an option in wind erosion control but is usually not economical or practical. Because land reshaping is very costly, other effective control measures, such as no-till and seeding to permanent grass, are usually options that are more viable. Hills and knolls affect tillage system requirements indirectly by influencing wind shear stress. When the wind blows over a hill, streamlines of airflow are squeezed together, which increases the wind velocity and shear stress, thereby increasing the erosion potential on the windward slope and hilltop. Consequently, this increases the amount of residue, cloddiness, or roughness needed to control wind erosion on the knoll.

OTHER WIND EROSION SITUATIONS

Wind Erosion on Irrigated Land

Wind erosion on irrigated land can be a serious problem in areas characterized by variable high-wind velocities, where the soils are organic or quite sandy and low in organic matter or where crop residues are inadequate. Under certain conditions, it is impractical and wasteful of water to irrigate frequently enough to prevent a finely pulverized surface

soil from blowing. The depth of drying may only be a fraction of an inch and the soil below this may be wet, but if the immediate surface is dry and the wind is strong enough, the top layer can erode unless the soil particles are consolidated into clods or protected by vegetation. The basic element in erosion control by tillage on irrigated land, as on dryland, is the creation of a rough, cloddy surface which will resist the force of the wind, decrease its velocity at the ground level, and trap moving soil. Sandy soils, usually found in irrigated areas, are far more difficult to protect by emergency measures than fine-textured soils.

Wind Erosion Control on Sand Dunes and Other Problem Areas

Wind erosion control on sand dunes and other problem areas require measures that are more intensive to get sand dunes in check. Dunes lack a soil profile because they are unstable and underdeveloped. The sand is fine, loose, and easily moved by wind. It has no organic matter, consequently retains little moisture for plants, and has inherently low fertility. Sand dunes and drift areas often require artificial barriers or cover for stabilization before vegetation can be established. These include oil, clay gravel, picket fence, brush, straw, and hay. Clay is effective but is expensive. Hay or straw can be used as temporary mulches on blowout or small areas of dune sand at road cuts, around dwellings, and other disturbed areas. They provide some organic matter, which is critical for successful dune plantings. The establishment of permanent vegetation is the final objective in the stabilization of dunes.

Other Non-Vegetative Erosion Protection

Some of the non-vegetative and processed vegetative materials used are gravel and crushed rock, various surface films such as resin-in-water emulsion (petroleum origin), rapid-curing cutback asphalt, asphalt-in-water emulsion, starch compounds, latex-in-water emulsion (elastomeric polymer emulsion), by-products of the paper pulp industry, and wood cellulose fiber.^[2] Several of these spray-on adhesives are available for temporary wind erosion control of vegetable seedlings on mineral soils. Some of the adhesives are relatively expensive, but a few are economically feasible on high-value crops threatened by serious blowing that cannot be controlled by other methods.

Wind Erosion: Environmental Effects

R. Scott Van Pelt

Wind Erosion and Water Conservation Research Unit, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Big Spring, Texas, U.S.A.

Abstract

Wind erosion is the movement and loss of soil, resulting from the interaction of a bare, loose, and dry soil surface with wind. Although wind erosion occurs in all continents and in all climates, it is most prevalent and its effects are most profound in arid and semiarid areas of the northern hemisphere. Wind erosion is a soil-degrading process that reduces soil productivity, damages crops, and may, in extreme cases, result in the burial of fertile soil horizons and structures. The most visible evidence of wind erosion is fugitive dust (soil-derived dust emanating from and transported beyond the boundaries of a source field) that may be entrained in global circulation patterns and transported hundreds or thousands of kilometers from the source. Global estimates of soil dust flux to the atmosphere range from 250 to 5000 Tg yr⁻¹ on an annual basis. Estimates of return flux to the surface of land areas range from <10 to >200 t km⁻² yr⁻¹, and yearly estimates of total flux to the world's oceans range from 532 to 851 Tg yr⁻¹. Some of the dust returns to the earth by the settling of larger particles from the atmosphere, but much more is scavenged by cloud formation and rainfall. Fugitive dust contains higher concentrations of organic carbon; basic cations such as calcium ion, magnesium ion, and sodium ion; plant nutrients such as nitrogen, phosphorus, potassium, and iron; and numerous trace metals than the soils from which it was derived. These chemical species contained on dust, especially when hydrated, have been documented to react with and catalyze reactions with other atmospheric particulates, colloids, and gases and therefore have an influence on rainfall chemistry, the chemistry of surface waters, and the fertility of midlatitude oceans. Soil dust has been documented to transport living organisms including bacteria, fungi, and algae. Atmospheric dust may also have an effect on climate forcing by absorbing solar radiation in the atmosphere and reducing the radiation flux on the earth's surface. This entry explores many ways that wind erosion and the resulting fugitive dust impact various environments on earth.

INTRODUCTION

Wind erosion is the result of wind impacting a dry, bare, and loose soil surface. Approximately 500 million hectares worldwide are susceptible to wind erosion, primarily in the arid and semiarid regions of the northern hemisphere. Wind erosion is a natural process that has resulted in the sculpting of landscapes and the deposition of fine soil particles in regions downwind of the actual erosion. Locally, wind erosion is a soil-degrading process resulting in the deflation of fertile topsoil, decrease in soil productivity and agricultural sustainability, disruption of commerce, and burial of fertile topsoil and man-made structures.

The fine particles that become entrained in the wind and transported great distances contain higher concentrations of organic carbon; basic cations such as sodium ion (Na⁺), calcium ion (Ca²⁺), and magnesium ion (Mg²⁺); plant nutrients such as nitrogen (N), phosphorus (P), potassium (K), and iron (Fe); trace metals; and soil contaminants than the soils from which they originated. Fugitive dust (soil-derived dust emanating from and transported beyond the boundaries of a source field) is an effective transporter of

living organisms such as bacteria, fungi, and algae and has been linked with human and environmental health problems. Soil dust reacts with and catalyzes reactions with atmospheric gases and pollutants, thus reducing the deleterious effects of acid rain and cleaning the atmosphere of other anthropogenic contaminants.

WIND EROSION AND DEPOSITION PROCESSES

Wind erosion and eolian (wind interacting with the earth's surface) processes are natural phenomena that have shaped the earth since time began. The eolian re-sorting of sand and smaller mineral particles from braided streams and beach environments has resulted in deep deposits of Loess in many regions of the earth. It has only been during the 20th century that wind erosion has been studied in depth and that an understanding of the controlling processes has been emerged. Furthermore, the specific study of the direct and indirect environmental effects is only a few decades old.

As wind blows over a surface, ephemeral gusts move particles in the sand to fine sand size range, which either

creep along the soil surface or become entrained in the wind. Most sand-sized particles do not rise more than 30 cm before returning to the surface, accelerated by the wind, with a significant horizontal component of motion. These saltating grains strike the surface with considerable force, releasing more saltating particles and abrading finer soil particles from soil aggregates and crusts resulting in plumes of dust.^[1] These finer particles are easily entrained into the turbulent eddies to heights often exceeding 2–3 km. The median diameter of entrained particles decreases as altitude increases. As the particles are transported downwind, the higher terminal velocity of the larger particles and the shallower transport depth cause them to settle from the atmosphere first and thus closer to the source. Particles <20 μm in diameter have much lower terminal velocities and may remain entrained and transported in the atmosphere for days or weeks. Particles return to the earth's surface primarily by gravity settling (dry deposition) and by inclusion in rain drops (wet deposition). A classic and thorough treatise on wind erosion processes is presented in *The Physics of Blown Sand and Desert Dunes*.^[2]

SOURCES AND MAGNITUDE OF SOIL DUST

The principal source regions of soil dust are arid and semi-arid regions of the northern hemisphere^[3] (Fig. 1). Large expanses of bare, dry, and often loose soil susceptible to wind erosion exist in these regions. It is estimated that more than half a billion hectare worldwide contributes to the atmospheric dust load. The exact amount of dust that is entrained from these regions is uncertain due to the variability among source regions, within individual source regions, among years, and the variability of estimation methods. Estimates of annual dust entrainment vary from 250 to >5000 Tg yr^{-1} . Deposition rate estimates vary from 10 Tg yr^{-1} to 200 $\text{kg km}^{-2} \text{ yr}^{-1}$ for land areas, and total deposition flux to the oceans has been estimated at 532–851 Tg yr^{-1} . Dust transported from North Africa is deposited in Europe, the Atlantic Ocean, North America, South America, Asia, and other locations in Africa. Dust transported from the great source regions of Asia is deposited in the North and Tropical Pacific basins, North America, Greenland, and Southeast Asia. Evidence from eolian Loess deposits worldwide indicates that the magnitude of dust transport was much greater in the geological past.

ON-SITE EFFECTS OF WIND EROSION

Areas subject to wind erosion may be impacted directly by the blowing sand and dust. Among the short-term direct effects near source areas are reduced visibilities, which impair commerce, endanger travelers, and temporarily destroy scenic enjoyment and recreation opportunities. On cropland, plants may be damaged or killed by sandblast injury. Although these effects impact human activities and

economic success, it is the long-term effects that are of the greatest importance. Wind erosion is a soil-degrading process that selectively removes the fine, chemically active portion of the soil. Fine particles have greater surface-area-to-volume ratios than the bulk soil and thus are more important to nutrient cycling and water retention. The loss of fine mineral particles and soil organic carbon results in a less productive soil and less sustainable agroecosystem.^[4]

Coarser particles are often deposited near the field margins and may bury fences or clog drainage features. In extreme cases of widespread soil degradation, wind erosion can contribute to desertification and desert encroachment.^[5] The destabilization of fragile sandy soils may result in the burial of more fertile soils (Fig. 2) and man-made structures, including buildings, irrigation canals, highways, and rail routes. Migrating dune fields may travel several kilometers per year. Desert encroachment has displaced human populations in several regions around the earth and continues to threaten human population centers and economic enterprise.

OFF-SITE EFFECTS OF WIND EROSION

Soil dust composed of very fine soil particles <20 μm in diameter may be transported hundreds or thousands of kilometers by global atmospheric circulation patterns before being deposited on the earth's surface.^[3] The characteristics of soil dust are determined by the surface from which it was entrained.^[6] As the primary source regions for soil dust are arid and semiarid areas, it is not surprising that the dust from these regions contains an abundance of basic cations such as Ca^{2+} , Mg^{2+} , and Na^+ , carbonate and bicarbonate minerals, and soluble salts. Soil dust also contains enriched concentrations of plant nutrients such as N, P, K, Fe, and trace metals important to biogeochemical cycles of ecosystems.^[7] Carbon in many forms, including soluble organic compounds, and pesticides and daughter products, is also transported on soil dust.^[8] Viable biological organisms such as bacteria and fungi^[9] have been documented on soil dust. These chemical and biological “hitchhikers” contribute nutrients to agroecosystems, open ocean areas, and watersheds, which may be deficient in one or more of these nutrients, and to the cycling of these nutrients. The fertilization of nutrient-deficient waters of midlatitude oceans may result in the proliferation of algal populations and thus may have a minor impact on global carbon cycles. It has been suggested that dust emanating from the Sahara Desert may be a cause of coral diseases in the Caribbean Sea.^[10]

Fine particles tend to be hygroscopic in nature, absorbing available water vapor from the surrounding air mass, and are very efficient condensation nuclei. As water condenses around the dust particle, soluble salts and organic compounds dissolve. The film of water around the particles in clouds also facilitates chemical reactions between the minerals present and the atmospheric gases and non-soil

Fig. 1 The global distribution of major dust sources and dust transport paths based on the Total Ozone Mapping Spectrometer aerosol product. The darker gray tones show those regions where substantial concentrations of dust are lifted into the air more than 50% of the time during the dusty seasons of the year. The arrows show the main transport paths over the oceans. The arrow size is not indicative of the magnitude of the transport or the distance that dust is carried.

particulates. In industrial areas with high fossil-fuel use, oxides of S and N are present in larger concentrations and are also dissolved in the rain, resulting in rainfall with much higher acidity. This acid rain has been credited with damage to forest and aquatic ecosystems. In areas frequented by high loads of soil dust, soluble basic minerals, primarily carbonates, partially or totally neutralize the acidity.^[11] Finally, the role of soil dust in radiative forcing of climate and the extent to which present and projected future dust levels may influence the earth's energy balance and temperature are in debate.^[12]

CONCLUSIONS

Wind erosion affects a large portion of the earth's surface, with direct effects in the source regions. The fine soil dust results from wind erosion may be transported to great distances and impacts the regions through which it passes and on which it is deposited. The input of basic cations, plant nutrients, soluble salts, soluble organics, and trace elements may be locally important sources for deficient ecosystems but may also have a deleterious effect on the quality of surface waters. However, dust may positively impact water quality in areas prone to acid precipitation. More research is

needed to quantify the effects of dust on environmental quality and climate.

Abstract

Wind erosion and deposition result when wind moves soil from a bare susceptible surface to another location downwind. Although placement of permanent vertical references such as pins or rods has been used to measure soil redistribution, it is more commonly measured by capturing sediment moving during an event. Through the years, several sampling devices have been developed to trap sediment in transport or to measure fine dust that may linger after a wind erosion event. Some of the devices are passive, meaning that they use the force of the wind and the momentum of the sediment to fill the sampler, and some are active, meaning that a stream of air is drawn through the sampler by a vacuum source. In addition to sampling sediment in transport and suspended in the atmosphere, methods have emerged that allow estimation of redistribution rates by comparing soilborne environmental tracer content on a landscape with the tracer content of a location in which no erosion or deposition has occurred.

INTRODUCTION

Soil is redistributed when the erosive force of the wind impacts a bare susceptible surface, entraining particles that travel a distance and then return to the surface. Accurate and reliable measurement of this redistribution is necessary in order to confirm and validate erosion models, to assess the magnitude of soil redistribution,^[1] and for other applications. Soil erosion is a degradative process that impacts soil productivity at the source, and the resultant fugitive dust impacts visibility, commerce, and environmental and human health. Of particular interest is the role that microorganisms transported on dust play in ecosystem processes and methods to sample for living microorganisms from dust suspended in the atmosphere.^[2] Wind-entrained particles are transported in three modes—Heavier, larger particles tend to roll along the surface in creep mode, slightly smaller particles tend to bounce along the surface in saltation mode, and the finest particles are levitated on wind eddies and may travel from a few meters to millions of meters in suspension mode. In general, there is no single sampling method that works equally well for all modes of transport.

SAMPLING CONSIDERATIONS

Measuring wind erosion may be accomplished by repeated measurement of the soil surface with respect to a reference such as a rod or pin driven into the soil^[3] or, more

commonly, by sampling and extrapolating from the amount of wind-entrained sediment moving during a wind erosion event. The exact type of sampling equipment used to collect wind-entrained sediment during and after an erosion event will vary depending on the mode and direction of particle transport. Sampling particles moving horizontally by creep and saltation may require sampling equipment that will quickly align with the direction of the wind, whereas sampling fine dust rising on atmospheric eddies may be accomplished with samplers that are not aligned with the wind field. Fine fugitive dust resulting from an erosion event may remain suspended after the end of the event and be deposited in a vertical direction during calm wind conditions or be washed from the atmosphere by rain.

Changes in the direction or velocity of the wind field may affect sampler efficiency. An ideal sampler for sediment moved by the wind should not only quickly orient the sampler opening into the wind but should also have openings that are isokinetic and relatively insensitive to rapid fluctuations of wind direction.^[4] Isokinetic means that wind enters the sampler at the same velocity encountered adjacent to the sampler. Due to the limitations of some sampler designs, samplers vary in terms of their sampling efficiency. If the sampler collects all the sediment that is in the wind field, then it is 100% efficient, and if it collects only half of the sediment in the wind field, then the efficiency is reduced to 50%. Samplers may be nearly 100% efficient for one range of particle diameters and much less efficient for other ranges of particle diameters, leading to sampling bias.

Many different types of sediment samplers and sensors have been used to measure wind-induced soil erosion and deposition.^[5,6] Samplers are either passive, relying on ambient wind fields to collect sediment samples, or active, relying on an external source of vacuum to pull sediment-laden air into the sampler. In general, passive samplers are primarily used to sample sediment in the creep and saltation mode, whereas active samplers are commonly used to measure fine suspended dust.

Passive Samplers

Passive samplers have the advantage for field measurement of not requiring external power sources and are thus relatively inexpensive to purchase and maintain. Passive samplers for measuring creep have either vertically oriented openings at ground surface or horizontally oriented openings very close to the surface. Perhaps the simplest creep sampler is a depression or series of depressions in the surface in which the creeping material is deposited. Inaccuracies may occur in this simple approach, as original surface material may be confused with the material transported by wind. A simple creep sampler may be made by burying a jar with a small hole in the lid so that the lid is even with the soil surface. Unfortunately, scour of surrounding material may result in the lid becoming superior to the soil surface and losing its supply of sediment transported in creep mode.

Combinations of creep and saltation samplers with horizontal openings have been designed by many researchers including Bagnold^[7] to measure creep and the vertical profile of saltating sediment particles. The Bagnold sampler (Fig. 1) is simply a vertical series of inclined pockets oriented into the expected direction of the erosive wind. The lowest opening had its opening at or slightly below the ground level and was connected to a subterranean sediment reservoir. Pockets above the lowest opening have their own reservoir at the bottom of the incline, but the sampler had a solid back and was not isokinetic. The Bagnold sampler has been found to be only about 20% efficient.^[5] However, by loosening the connection between the lowest slot and the reservoir, the efficiency may increase to 50% as less back pressure will be created at the sampler opening.^[5] Chepil improved on the Bagnold design by mounting the sampler on a rotating plate and adding a wind vane to keep the openings oriented into the wind.^[8] Other improvements through the years have included changing the shape to a wedge with the small end oriented into the wind and adding fine screen to improve the air flow into and through the sampler. A wedge-shaped slot sampler with an opening 50 cm high and 2 cm wide with a fine screen on the back has been found to be over 90% efficient for creep and saltation-sized particles.^[3]

U.S. Department of Agriculture has developed a creep and near-surface saltation sampler (Fig. 2) that is installed flush with the surface and has openings at 0–3, 3–9, and 9–20 mm above the surface.^[9] The sampler is built so that

Fig. 1 Schematic diagram of a Bagnold sampler.

the openings and subtending sediment reservoirs can rotate and stay oriented into the direction of the wind. Companion saltation and suspension samplers for this near-surface sampler are wedge-shaped with screened air outlets and may be mounted on a vertical shaft at multiple arbitrary heights above the surface.^[10] These samplers have become very popular for wind erosion studies globally and are known as Big Spring Number Eight (BSNE) samplers. They may be purchased or fabricated with single large openings or with three BSNE samplers linked together with smaller openings for collecting samples near the ground (Fig. 3). The efficiency of the BSNE has been found to exceed 90%.^[10]

A very inexpensive and popular sampler for measuring saltation and suspension is the Modified Wilson and Cooke (MWAC) samplers.^[11] These are easily fabricated using bendable tubing and bottles (Fig. 4). Since the early 1990s, MWACs and BSNEs have been the saltation and suspension samplers of choice by the international Aeolian

Fig. 2 Creep-saltation sampler (top) and close-up of the sampler openings (bottom); a dime is placed in front of the sampler openings for scale.

community. Both samplers have high efficiencies and are easy to use in field studies but collect the samples over a time period defined by the frequency of sample collection. Passive samplers have been developed that measure the high-frequency temporal variations in sediment transport by placing the saltation and creep sampler over a buried box containing either a microbalance^[12] or a tipping bucket.^[13] Other passive samplers are available with load cells integrated into their design so that sediment is automatically weighed as it is collected (Fig. 5).

Temporal variations of saltation may also be measured with electronic sensors of various types. Among the first electronic sensors, the Saltiphone (Fig. 6) utilized a microphone capsule behind a protective cover that was mounted on a finned tube to pivot into the wind. An impact by a saltating sand grain or aggregate created a sound resulting in an electrical impulse that could be recorded by a data logger. Other sensors such as the Sensit (Fig. 7) and Safire utilize piezoelectric crystal sensors to create the electrical impulse. They have an advantage over the Saltiphone by being cylindrical and not needing to pivot into a rapidly changing wind field. These saltation impact sensors have been tested, and their performance compared in a laboratory wind tunnel utilizing different particle diameters and

Fig. 3 BSNE sampler mast. Note that the lowest section is composed of three samplers mounted together, and the lowest two samplers have smaller openings.

wind speeds.^[14] Electronic sensors utilizing optical technology (Fig. 8) have been developed and used in Aeolian studies.^[15] The user should clean the optics often to obtain reliable saltation data with these sensors. The rapid response of these electronic sensors has permitted the development of a localized definition of threshold wind velocity based on the percentage of time that sediment is being transported by an observed wind field.^[16]

Suspension Samplers

Particles finer than 100 μm in diameter may become entrained in turbulent eddies, transported horizontally and vertically, and lifted to great heights during wind erosion events. Once lifted to high altitude, the particles, especially the finer ones, may travel hundreds to thousands of kilometers in a dust haze before returning to the earth by gravity. Passive samplers such as moss and pans or buckets containing marbles (Fig. 9) have been used to measure dust fall. Pan-type samplers containing marbles to prevent resuspension of the captured dust are easily and inexpensively

Fig. 4 MWAC sampler mast. Individual samplers are easily constructed using tools and items locally available.

built using an aluminum angel food cake pan with 250 mm diameter and 100 mm depth and thus have been used extensively in regional dust deposition studies.^[17] These are typically mounted atop a pole at a height of 2 m above the ground in a non-eroding, vegetated area. Some method to discourage bird perching on the sampler should be employed to prevent fecal contamination.

Fig. 7 Sensit particle impact sensor.

Fig. 8 Wenglor optical particle counter mounted for field studies.

Saltation samplers such as the BSNE and MWAC also collect some horizontally moving suspension-sized sediment. The MWAC has been found to be nearly twice as efficient at trapping fine suspension-sized sediment compared to the BSNE.^[1] This study also indicated that

Fig. 9 Pan-type dust collector with marbles. The pan diameter is 250 mm, and the metal bands crossing over the top discourage bird perching.

the efficiency of the BSNE was constant, whereas the efficiency of the MWAC varied with wind speed.

Active sampling devices using mechanically generated suction are often used to sample suspension-sized sediment from moving and stationary air bodies. Many of the devices draw air through a filter that is periodically removed and weighed. Among the first to use this method of sampling, Chepil and Woodruff used aspirated 48-mm filters mounted at 4 heights to measure dust in Kansas and Colorado.^[18] Today researchers can buy large or small self-aspirated filtering devices that many municipalities use to monitor air quality. A relatively new development is the Tapered Element Oscillating Microbalance (TEOM) that draws air through a small filter and weighs that filter at regular intervals to provide a history of dust concentration. For more frequent measurement of dust concentration in the air, optical sensors designed to monitor air quality in industrial

Fig. 10 USDA-ARS fine particle dust sampling head attached to a dust monitoring system (top) and close-up of sampling head (bottom).

settings may be used. Such devices with horizontal tubes that pivot into the wind (Fig. 10) have been used to frequently and quasi-isokinetically sample dust at multiple heights above the ground at several downwind locations over an eroding field.^[19] The entry successfully showed a link between temporal variability of saltation and vertical dust flux.

TRACER-BASED METHODS

Soilborne tracers that have appeared at a unique time in history may be used to estimate soil redistribution rates on the landscape at a decadal timescale. An example of this would be the use of coal fly ash in the soils adjacent to rail lines in which coal was burned in locomotives from the middle 19th century to the middle 20th century. By comparing the amount of time-stable tracer material on a landscape with suspected soil redistribution with the content in the soil of a known stable landscape such as a well-grassed hilltop or courthouse lawn, the difference in tracer content can be linked to soil redistribution. The advantage of this approach includes the necessity for only one trip to sample the soil profile at several locations in the landscape of interest. The most commonly used tracers for this type of soil redistribution measurement are anthropogenic radioisotopes such as ¹³⁷Cs, an isotope of cesium that did not exist in more than trace amounts prior to the atmospheric testing of nuclear weapons in the late 1950s and early 1960s. Anthropogenic radioisotopes have been used to estimate average rates of soil redistribution on nearly every continent of the world.^[20] In addition to anthropogenic radioisotopes, naturally occurring isotopes with relatively short half-lives such as ²¹⁰Pb and ⁷Be have also been successfully used to estimate soil redistribution rates at less than decadal timescales. Finally, chemical tracers such as rare earth elements may be applied to the surface soil layer and tracked on the landscape.

CONCLUSION

Many sediment sampling devices, both passive and active, as well as other methods exist to measure various spatial and temporal aspects of wind erosion. Many of the passive devices are easily and inexpensively constructed and have been extensively used by researchers globally. Other technologies are somewhat more expensive and used for specialized studies of Aeolian processes. Robotics (Fig. 11) offer a unique opportunity to deploy sampling equipment^[21] to investigate Aeolian processes at multiple spatial scales. With advances in technology, routine rapid measurement of wind fields, saltation, and dust concentration may become more affordable and subsequently routine.

Wind Erosion: Global Hot Spots

Andrew Warren

Department of Geography, University College London, London, U.K.

Abstract

“Natural” can be differentiated from “induced” erosion; this entry concentrates on the latter. Hot spots vary both in time and space; they come and go and their intensity varies from place to place. A hot spot is assumed to be where the rate of wind erosion is well above the mean, even though it may not have serious economic impact. Hence, the Dust Bowl of the Great Plains in the 1930s was probably a hot spot, yet, agriculture is prosperous there. There and elsewhere, as in the West African Sahel, the Mallee of south-eastern Australia, a great deal of soil may be lost without much impact on yield, until the last few centimeters of soil are left.

NATURAL EROSION

The Sahara, the Central Asian Deserts, and the Chinese deserts are the sites of very high rates of “natural” erosion. Much more sediment leaves the Sahara in wind than in water. Contemporary outputs from the Sahara are of the order of 10^9 tons per year.^[1] Dry Australia, the southwestern United States, and southern South America are less important but still significant natural hot spots. The dust reaches far into the oceans and beyond, as from northern African to the United States and from Australia to New Zealand (Fig. 1). Marine and land sediments (Loess and stabilized sand dunes) show that the hot spots were hotter in the Pleistocene, and that they got hotter as it progressed. In the Central Sahara, Egypt, western Argentina, eastern Iran, and parts of western China, great grooves were cut at those times by wind erosion, some in hard rock. There were also more hot spots, as in parts of Northern Europe and Central North America. Ice core data from Greenland, the Tibetan Plateau, and the Antarctic corroborate the picture. The contemporary global source areas are all very dry. Explanation of the temporal change is more disputed.^[2]

Seen at a finer scale, most “natural” erosion in these deserts occurs in soft sediments, particularly those in ancient, dry lake basins. The northern Chad Depression in the central Sahara and the Lake Eyre basin in Central Australia are major natural hot spots.^[3] In the late Pleistocene, the bare outwash plains around glaciers were the sources of Loess and sand that formed dunes (mostly stabilized) in northern Europe, Asia, and northern Canada. People have little influence on rates of wind erosion in deserts. There are exceptions. Off-road vehicles create a minor hot spot in the Mojave of southern California; and wars and training for wars have created other hot spots in North Africa during the 1940s and during the Gulf War.^[2]

INDUCED EROSION

Identifying global hot spots of induced wind erosion is more problematic. Measurements of emissions are very few indeed, measurements of rates of erosion are even fewer, and measurements of economic impact are the rarest of all. This leaves some results from modeling, historical accounts built on disparate evidence, and informed guesses. Modeling and measurement suggest short-term rates of the order of $30\text{--}60 \text{ t ha}^{-1} \text{ yr}^{-1}$ on dry High Plains sites, depending on winds, rainfall, and land use. Caesium-based measurements in the Sahel of West Africa, on sandy soils under fallow cultivation cycling, and with mean annual rainfalls of about 550 mm give rates of up to $40 \text{ t ha}^{-1} \text{ yr}^{-1}$ over a 30-year period.^[4]

Some historical accounts are well documented and compelling. The Dust Bowl of the American Great Plains in the 1930s was an undisputed hot spot.^[5] Dust storms were more frequent and violent and many farmers went out of business, though more from drought than erosion. There were renewed hot spots here in the 1950s, 1960s, and 1970s, on the evidence of agricultural surveys and dust emissions. Probably more serious, though less well documented, at least in English, were the hot spots in the Soviet Union, specially northern Kazakhstan and neighboring parts of Russia, at about the same time^[6] (although the earliest recorded paper in Russian on wind erosion control was written in 1768). More surprising, even to some experts, are histories of wind erosion in Western Europe. An even earlier paper on wind erosion, titled “A curious and exact relation of a sand cloud which hath lately overwhelmed a great tract of land in the county of Suffolk” appeared in the *Philosophical Transactions of the Royal Society of London* in 1669. In Sweden, no less a person than the great naturalist Linnaeus recorded destitution because of wind erosion in Skania in the 18th century. There is similar evidence in northern Germany, The Netherlands,

Fig. 1 Global hot spots for wind erosion.

Denmark, Poland, and Hungary. Archaeology shows that there were hot spots as far back as the Neolithic, when ancient farms were buried in sand in southeastern England and The Netherlands. In all these areas, it was and is sandy soils, inherited from glacial outwash, that are the most susceptible. The period of desiccation in the Sahel of West Africa is said to have been a hot spot for wind erosion. Some evidence lies in dust-storm data^[1] and, as in the Great Plains of the 1930s, there was undoubtedly great hardship. However, here too, the exact role of wind erosion is debatable. Much of the dust may have come from quite small perimeters round dust-measuring stations, and the hardship was to do more with drought than erosion.

Informed guesses are a more dubious source. The literature is no great help, even with the wind erosion bibliography (listing works till 1995) and its 2700 odd entries.^[7] It is undoubtedly biased toward work in English and toward areas where funds have been more available and to places where there has been a strong scientific tradition. For example, research in the United States, and the Great Plains in particular, where massive funds for research were released and maintained after the 1930s, overwhelms the bibliography, yet the aforementioned historical evidence suggests that the problem may have been more serious in the Union of Soviet Socialist Republics. Indeed, Petrov's bibliography of relevant work in Russian (1768–1950) has 852 entries. Germany, with its long scientific tradition, apparently dominates research in Europe, yet it is known that the

problem is as serious in neighboring countries. Southeastern Australia is also, by this evidence, a hot spot,^[8] yet in terms of damage to cropland, the Sahel of West Africa is probably more of one (the Sahel is only belatedly receiving scientific attention). Using the literature, Crosson^[9] estimated that the Sahel was a major wind erosion hot spot, yet there are few data on which to base this conclusion.^[4]

Only one systematic attempt at informed guessing on a worldwide scale has been made. This is GLASOD (The *GL*lobal *AS*essment of *SO*il *D*egradation). It is most accessible in the *World Atlas of Desertification*, which is in its second edition.^[10] The assessment was for “polygons” of the order of size of southeast England, the province of Skania in Sweden, or a quarter of an average U.S. State. Experts who knew each polygon were asked a set of carefully constructed questions about the extent and severity of soil degradation, including wind erosion. The result is the best guess we have of the severity of wind erosion globally. But it has serious flaws: in Africa and many other parts of the world, there were no measurements at the time of the questionnaire against which to compare the guesses; the distinction between induced and natural erosion is unclear; some experts have interpreted the questions differently from others; the identifications are generally of potential rather than actual erosion; and the polygons are huge.

The expert opinion used in GLASOD is based on our scientific knowledge about wind erosion. If, as a simple framework, we take the factors in the famous Wind Erosion

Equation of Woodruff and Siddoway, we can follow it in predicting the hot spots.^[11] Three factors are almost equally important. First is the climatic (C) factor. Most induced wind erosion occurs in areas with semiarid climates, as corroborated by maps of the C factor in the Sahel of West Africa and in the United States. This is also true in the Union of Soviet Socialist Republics, Australia, and north-western Europe. However, wind erosion can and does take place in much wetter climates. In Wales and in the Pennine Hills of England, peat is blown away after fires and in long dry spells. Erosion occurs in parts of England, where the mean annual rainfall is of the order of 1500 mm. At roughly the same mean annual rainfall, there is also significant wind erosion on the coastal plain of South Carolina. Wind erosion is reported in the Austrian Tyrol, where rainfalls approach 2000 mm. Even in Iceland, where evapotranspiration is very low, there is some serious wind erosion. The C factor is also important in the temporal dimension: when there are dry years, wind erosion hot spots appear, as in the Dust Bowl and the Sahel.

The K, or soil, factor in the Wind Erosion Equation is the second important control, for wind erosion rarely affects fine-texture soils, although a few may be "pelletized" into aggregates of sand size, which may then be moved by the wind. Areas with agriculture on sandy soils are, worldwide, the common locations of hot spots, because they lack binding agents for aggregation. Peats which also may be loose are also eroded in Western Europe and Florida, when they are drained, cleared, and cultivated. Light Loess soils, as in the Palouse of Washington State, parts of the Great Plains and the Russian steppes, are other hot spots.

The last crucial factor is vegetation cover, and this is the most susceptible to management. The plowing or harrowing of a field can raise considerable quantities of dust,^[12] but its clearance of vegetation in dry and windy seasons is the more generally damaging. The reasons why farmers clear susceptible fields are exceedingly complex. Ignorance may sometimes produce a minute hot spot, but it is an inexperienced farmer indeed who does not realize that erosion follows clearance. In the Sahelian hot spot, for example, the laying of millet (*Pennisetum glaucum*) stalks to counter erosion is a standard practice. Economic forces produce the main hot spots for induced erosion. In Europe, at least, the short-term economic impact of wind erosion does not provide a strong enough incentive to persuade farmers to manage it. Worster believed that the huge hot spot in the U.S. Dust Bowl was mainly due to farmers being driven to cultivate by other economic forces, such as the

need to pay off loans from banks and from machinery salesmen. The massive Soviet hot spots are said to have been the result of yet another kind of economic force: centralized and ill-informed attempts to reach U.S. standards of economic output. In our study of a village in Niger, economics takes yet another guise: wind erosion is the outcome of a gamble by those farmers who can afford to lose a crop, because they have other economic options.^[13]

Wind Erosion: Micrometeorology

Giles F.S. Wiggs

Department of Geography, University of Sheffield, Sheffield, U.K.

Abstract

Wind erosion of soils and sediments can be considered at a number of temporal scales ranging from sub-second to annual or greater. Agricultural scientists often refer to amounts of erosion in terms of tonnes per hectare per year or equivalent, but, while such terms are useful for comparison between fields, they mask many of the dynamic processes operating on the soil at much smaller spatial and temporal scales. In order to fully appreciate wind erosion, it is important to have an understanding of the smaller-scale processes that are operating at timescales ranging from seconds to minutes or hours. It is processes operating at this microscale that control the local erosivity (erosive power) of the atmosphere and can have an impact on the erodibility (susceptibility to erosion) of soils. Such meteorological factors include wind shear stress, wind turbulence, thermal stability, and humidity.

VELOCITY PROFILE, WIND SHEAR STRESS, AND SURFACE ROUGHNESS

As wind moves over a soil surface, it is retarded at its base by friction from the roughness of that surface. This creates a velocity profile with a region very close to the surface of zero velocity and wind high in the profile (or boundary layer) unaffected by the surface friction (called free stream velocity). The depth of this zero-velocity layer (termed z_0) is called the aerodynamic roughness length. It is an important parameter because it partly controls the gradient of the velocity profile, which is proportional to the shear stress (or force) of the wind on the surface. When wind shear stress at the surface reaches a critical level, wind erosion will occur.^[1]

Under normal atmospheric conditions, a wind velocity profile plots as a straight line on a logarithmic chart, the gradient of which is proportional to the surface shear stress. It is simpler to measure velocity profiles than it is to measure surface shear stresses, and so the gradient of a velocity profile (equivalent to shear velocity, u_*) is often used as a surrogate for surface shear stress.

The relationship between surface shear stress (τ_0) and shear velocity (u_*) is given by the following formula:

$$u_* = \sqrt{\tau_0 / \rho} \quad (1)$$

where ρ is air density.

From measurements of a simple mean velocity profile, an assessment can therefore be made of the shear stress imparted by the wind to the surface. High shear stresses are associated with high mean wind speeds, but many other factors also have an influence.

CHANGES IN SURFACE ROUGHNESS

One of the most important controls on shear stress is the roughness of the surface and its effect on the value of aerodynamic roughness, z_0 . Any change in the value of z_0 has a subsequent effect on the velocity profile gradient because of the alteration in the depth of the zero-velocity region. With all other factors remaining the same, an increase in z_0 will lead to an increase in u_* (and hence surface shear stress) and vice versa (Fig. 1).

The wind will respond to surface roughness at a variety of spatial scales. At a small scale, the individual soil clods create a drag on the airflow, as do ploughed furrows or crops. At a larger scale, shelterbelts, fences, and hummocky terrain also affect the velocity profile (Table 1). As the wind blows across a single field, it will respond to these changing surface roughnesses and so too will the shear velocity, surface shear stress, and the ability of the wind to entrain and transport soil particles. Rough surfaces should therefore be more susceptible to wind erosion than smooth surfaces. However, the relationship is complicated by the fact that increases in surface shear stress caused by a larger value of z_0 may not necessarily lead to increases in sediment entrainment and transport. This is because any increase in surface roughness may result in more grains lying within the depth of z_0 and hence protected from erosion in a layer of zero-velocity flow. This is the reason why fields ploughed perpendicular to the mean wind direction can often be stable and resistant to wind erosion, as the aerodynamic roughness height caused by the furrows allows the protection of fine surface soil. Typical values of z_0 for different surfaces are shown in Table 1.

Fig. 1 Velocity profiles showing a focus at height z_0 , the aerodynamic roughness length. The aerodynamic roughness in (A) is less than in (B); hence, shear velocities (u_*) in (B) are greater.

Source: From Wiggs.^[1]

ROLE OF TURBULENCE

The semilogarithmic wind velocity profile (Fig. 1) only occurs under mean wind conditions, averaged over time periods ranging from perhaps 30 seconds or greater. However, under most natural conditions, wind in the environment is turbulent and consists of high-velocity gusts and low-velocity troughs. For this reason, velocity profiles measured over timescales of the order of 1 second do not display a semilogarithmic relationship with height.

In a turbulent velocity profile, momentum transfer through the profile is achieved by turbulent eddies of varying sizes. These operate in a cascade from eddies as large as the boundary layer to viscous energy dissipation at the

surface. These eddies move between different layers of fluid and impart or absorb energy depending on whether the eddy is faster or slower moving than the surrounding air.^[3] This type of momentum transfer is very efficient and results in high mean shear stresses being imparted to a soil surface.

Research^[3,4] suggests that sediment entrainment and transport can be greatly influenced by peak values in instantaneous shear stress provided by these turbulent flow structures (Fig. 2).

Three types of important turbulent structure have been identified as follows: 1) eddies of low momentum fluid at the surface elevated into faster air above (“burst” events); 2) high momentum fluid from high in the velocity profile impacting the surface (“sweeps”); and 3) flow-parallel longitudinal vortices (“streaks”).

Each of these flow structures may have periodicities of around 20 Hz and is considered to be critical in wind erosion because they may provide instantaneous peaks in shear stress which might exceed the threshold of grain entrainment, even where the mean wind velocity is just below that threshold. In these circumstances, turbulent flow structures may provide high instantaneous shear stresses which could entrain a few grains into saltation. These grains may then be kept in transport by the mean wind velocity (as the energy required for sediment transport is less than that required for entrainment) and, on impacting the surface, splash other grains into transport. In this way, a few saltating grains entrained by turbulent

Table 1 Typical aerodynamic roughness (z_0) values for different surfaces.

Surface	z_0 (m)
Sand	0.0003
Rippled sand	0.003
Soil	0.001–0.01

motion may provide a downwind cascade of entrainment and result in significant wind erosion.^[1]

THERMAL STABILITY

The logarithmic relationships shown in Fig. 1 only arise in atmospheric conditions with neutral buoyancy. Such conditions are found with cloudy skies (which reduce radiative heating) and strong winds (which promote atmospheric mixing and prevent temperature stratification).^[2] On clear and sunny days (especially in arid or semiarid areas), strong radiative heating may result in thermal instability (with a steep temperature gradient), which increases buoyancy effects and vertically stretches turbulent eddies. This results in a reduction of the wind gradient (becoming more vertical with height, in Fig. 1) with atmospheric turbulence driven by buoyancy effects rather than mechanical forces. Conversely, atmospheric stability (often occurring at night with radiative cooling of the surface) tends to squeeze turbulent eddies vertically resulting in a strong wind gradient (becoming more horizontal with height in Fig. 1) with little vertical mixing.

Both atmospheric stability and instability therefore have an impact on the structure of the velocity profile and hence on the shear stresses evident at the surface. The impact of thermal stability or instability on wind erosion is a function of the role of turbulent eddies. Atmospheric instability is associated with greater vertical mixing of air, and so fast-moving upper air is commonly brought closer to the surface resulting in an increase in shear stress. In contrast, a stable atmosphere is associated with relatively low surface shear stresses because turbulent mixing is damped down.^[5]

Sediment transport and wind erosion are therefore more likely to be evident where the atmosphere displays thermal instability (rather than stability) because buoyancy forces result in strong vertical mixing and increased turbulence. However, atmospheric instability is also associated with low mean wind speeds, and such conditions are unlikely to result in significant erosion. Wind erosion is more closely associated with neutral atmospheric buoyancy where a reasonable amount of turbulent mixing is combined with high mean wind

speeds. As noted, such conditions are generally associated with overcast skies and high winds during the daytime.

CHANGES IN HUMIDITY

Humidity refers to the water vapor content of the atmosphere, and it is an important variable in wind erosion because of the two-way transfer of water vapor between the soil surface and the near-surface atmosphere. This transfer has large implications for the erodibility of a soil.

Grain entrainment is a function of the ratio of resisting forces to dynamic forces.^[1] While grain size is the most important of the resisting forces, considerable resistance to movement can be provided by moisture in the upper layers of the soil. The exact physical nature of the relationship between grain entrainment threshold and moisture content has yet to be quantitatively defined, but there is a theoretical basis for suggesting that the threshold rises as a function of surface tension associated with pore moisture.^[6] Humidity has an important role to play here because an unsaturated air mass (low humidity) will have a significant drying effect on a soil and thus increase its erodibility (lowering the threshold of grain entrainment), while a saturated air mass will have the opposing effect. Research has suggested that the threshold of grain entrainment might be very sensitive to changes in moisture content below about 4–8%.^[6] Fairly small changes in atmospheric humidity may therefore have a critical impact on grain entrainment and wind erosion.

FUTURE DIRECTIONS FOR MICROMETEOROLOGICAL RESEARCH

A major challenge in wind erosion research is to successfully link the differing scales of investigation and applied activity. It is clear that an understanding of erosion processes at the microscale is necessary to successfully comprehend the wind erosion system, and many advances have been made toward this end. However, the application of this understanding is often at the field scale or larger, and it is in the transference of

scales where failure has occurred in the past. Process measurements operating over timescales of seconds or hours cannot easily be linked to changes in field erosion which may occur over timescales of months to years. As scales of interest increase, the reliability and appropriateness of small-scale process work on wind erosion decrease. It has been argued that, where appropriate, small-scale process measurements should become checkpoints for model calibration.^[7] In this respect, micrometeorology is likely to become increasingly important in soil erosion models for the prediction and assessment of wind erosion.

Wind Erosion: Modeling

Lawrence J. Hagen

Wind Erosion Research Unit, U.S. Department of Agriculture—Center for Grain and Animal Health Research (USDA-ARS-CGAHR), Manhattan, Kansas, U.S.A.

Abstract

Models of wind erosion are used to investigate fundamental processes and guide resource management. Many models are similar in that temporal variables control soil wind erodibility, erosion begins when friction velocity exceeds a threshold, and transport capacity for saltation/creep is proportional to the cube of friction velocity. The conservation of mass equations that incorporate erosion processes has been developed to calculate soil loss, transport, and deposition. Components of the Wind Erosion Prediction System model are illustrated as an example.

INTRODUCTION

Numerous models of wind erosion exist. In regional- and global-scale models, dust generation is often coupled to diffusion, advection, and deposition models.^[1] Their applications include the prediction of dust impacts on past climates,^[2] military operations,^[3] health problems,^[4] and existing weather, particularly in East Asia.^[5] Model results also demonstrate that dust is an important contributor to climate forcing.^[6] There are numerous challenges in modifying field-scale models for use on large areas.^[1,7–9]

Field-scale erosion models are used to predict soil loss, plan conservation systems, and assess off-site impacts of wind erosion.^[10,11] Many models exist to simulate specific effects such as sand ripples.^[12] Models also serve to increase and synthesize our knowledge about wind erosion of soil.

WIND EROSION PROCESSES

The major factors that control soil wind erodibility are mainly temporal (Table 1), and their range of variation depends on weather, soil management, and soil intrinsic properties such as texture.

To begin erosion, friction velocity must overcome the forces holding particles on the surface. Threshold friction velocities for dry, monodisperse particles have been measured^[13] and theoretically analyzed (Fig. 1).^[14] For mixtures of sizes, thresholds may be slightly lower due to particles perched on a surface or higher when sheltered by immobile aggregates.^[15] Both surface wetness and high humidity also tend to increase threshold velocities.^[16,17] Saltation is not needed to entrain 0.07–0.10-mm-diameter particles. Abrasion creates mobile aggregates, and abrasion susceptibility of clods/crust can be characterized by an abrasion coefficient. It can be directly measured or estimated from the crushing energy.^[18,19] Intermittent field

erosion in the short term is often caused by wind gustiness,^[20] but longer term variations may be caused by surface armoring during erosion events.^[21]

Modes of soil transport include creep (rolling, 0.8–2.0-mm diameter), saltation (hopping, 0.1–0.8 mm), and suspension (<0.1 mm). The creep/saltation transport capacity q ($\text{kg m}^{-1} \text{s}^{-1}$) is proportional to the cube of friction velocity u_* (m s^{-1}). Many formulas for q have been proposed,^[15] and one formula is as follows

$$q = \frac{C\rho_a}{g} u_*^2 (u_* - u_{*t}) \quad (1)$$

where C is a coefficient, ρ_a (kg m^{-3}) is air density, g (m s^{-2}) is acceleration of gravity, and u_{*t} (m s^{-1}) is threshold friction velocity. The transport capacity for suspended particles is large, and their downwind discharge can be

Table 1 Factors that control wind erodibility of a dry, bare soil.

Soil state	Factors
Aggregated (tilled) surface	Aggregate size distribution by layer
	Dry stability of immobile aggregates by layer
	Breakage coefficient of mobile aggregates
	Rock volume fraction (>2 mm diameter) by layer
Crusted and/or consolidated surface	Random and oriented surface roughness
	Crust cover fraction
	Dry stability of crust/consolidated zone
	Thickness of consolidated zone
	Mass, cover, and breakage coefficient of loose soil on crust
	Other parameters same as aggregated surface

several times that of saltation/creep as illustrated by measurements at dry Lake Owen.^[22]

Wind erosion on a field scale can be modeled using the conservation of mass equations in successive control volumes each a few meters in length (Fig. 2).^[23] Friction velocity above standing biomass is depleted to simulate wind friction velocity at the soil surface. Sources of saltation/creep discharge include entrainment of loose aggregates by wind drag and splash impacts, and abrasion from immobile clods and crust. Sinks for saltation/creep discharge include trapping by surface roughness, interception by standing biomass, and breakage to suspension-sized particles.

Similarly, sources for suspension discharge include entrainment of loose aggregates, abrasion from clods and crust, and breakage of saltation/creep aggregates. Sinks

for suspension include interception by standing biomass and deposition on downwind immobile surfaces. Emission, abrasion, and breakage are modeled separately because the interparticle-binding energy increases by roughly an order of magnitude between each process. Moreover, not all processes may be present in a given surface condition, but each can be measured separately using a wind tunnel.^[24,25] Analytic solutions for quasi-steady-state conservation of mass equations have been developed for saltation/creep and suspension discharge^[23] and the predictions validated using measured data from small fields.^[26–28]

Field-Scale Wind Erosion Models

The most widely used model has been the empirical Wind Erosion Equation (WEQ).^[29] The long-term annual soil loss per unit area (E) is given by the following formula

$$E = ICKLV \quad (2)$$

where the factors are soil wind erodibility (I), climate (C), surface roughness (K), field length (L), and vegetation (V).

A continuous, process-based model, the Wind Erosion Prediction System (WEPS), has been developed (Fig. 3) to replace WEQ.^[30] In WEPS, weather simulators drive five submodels that simulate surface conditions on a daily basis and erosion on a subhourly basis.

Additional models used to predict erosion include the Revised Wind Erosion Equation, Texas Tech Erosion Analysis Model, Wind Erosion on European Light Soils, Australian Land Erodibility Model, and Integrated Wind Erosion Modeling System.^[31–35]

Wind Erosion: Principles

Larry D. Stetler

Department of Geology and Geological Engineering, South Dakota School of Mines and Technology, Rapid City, South Dakota, U.S.A.

Abstract

Erosion of sediment and soil by wind arises when the kinetic energy in the passing airstream exceeds the energy employed in adhering the grain to the surface. Initial grain motion is achieved at this instant, and the grain will be transported in saltation as a series of short hops along the surface. Each time the grain impacts the surface, additional grains are released into the flow until at some distance the carrying capacity of the wind is reached. From this point on, the mass of sediment in transport remains relatively constant, i.e., it is self-balanced. However, mass is lost from the process primarily through the deposition of heavy particles behind surface roughness elements. In addition, suspendable particles of fine dust are released vertically through the saltation layer. Many additional factors, such as climate and surface conditions, complicate the simple mechanics involved.

EROSION PROCESSES

Erosion of fine-grained sediment and soil particles by wind is a natural geologic process occurring worldwide on a nearly continuous basis. Throughout the geological record, evidence of wind processes eroding, transporting, and depositing sediment exists primarily as vast accumulations of eolian (wind-blown) sand—both modern sand dune fields and ancient eolian sandstone formations—and Loess (wind-blown silt). About 30% of the total land surface of the planet consists of semiarid and arid lands which give rise to most of the transported sediment and dust. Modern agriculture and industrial activities are also a significant contributor to transported sediment and dust due to induced or mechanical destabilization of the land surface.

Conceptually, the mobilization of loose sediment and soil particles occurs during wind storms or wind “events,” where the mean wind speed exceeds a critical threshold value based on some erodible fraction of the sediment. Individual wind events may be of short (less than one to a few hours) or long (multiple hours to days) duration. In terms of distance and total mass moved, a typical erosion event will transport the greatest mass a short distance and a significantly lesser mass a greater distance. The perception of moving sediment, however, may make this statement appear to be contradictory since there is, generally, an abundance of the smaller and lighter particles which are visually acute when airborne. Exceptional, or non-typical, wind events are able to transport fine particles across entire continents and oceans to distant lands where visual impacts to air quality may be readily observed.

Knowledge of particle entrainment and transport studies were greatly advanced through the work of Bagnold who used field observations in the deserts of Egypt and later wind tunnel studies to detail the mechanics of the erosional and transportation process. This work resulted in his well-known and widely used treatise *The Physics of Blown Sand and Desert Dunes*.^[1] He observed that once a particle begins to move it will be transported by one of three modes: creep, saltation, or suspension. The primary difference in these three transport modes is a relatively simple relation between the particle size and the wind force which, unfortunately, becomes a complex mechanical problem that is not fully understood.

WIND DYNAMICS

Wind is by nature a random process and as such, the internal structure of a natural wind contains random variations known as turbulence (except in possibly very stable conditions). Turbulence develops in natural flows as inertial forces, which provide forward momentum (motion), react to viscous forces, which impede motion due to fluid properties. This results in a flow that is strongly sheared.

The unit of measure for wind speed is the mean wind velocity, $\bar{U}$, defined as an average value for a continuous time series of instantaneous velocities (Fig. 1)

$$\bar{U} = \frac{\sum u_1 + u_2 + \dots + u_i}{T} \quad (1)$$

where $u_1 + u_2 + \dots + u_i$ are components of instantaneous velocity and T is the time interval over which velocity values are summed.

Fig. 1 Time series of 1-minute wind speeds illustrating the principles of determining mean wind speed, instantaneous, and fluctuating values.

Source: Unpublished data from author.

As shown in Fig. 1, at every instant a fluctuating component of velocity, u_i' exists defined as the difference between the instantaneous and the mean velocity values

$$u_i' = u_i - \bar{U} \quad (2)$$

It is these velocity fluctuations, whether positive or negative in regard to the mean velocity, that give rise to flow instability and thus turbulence. As such, turbulence is not a property of the fluid but of the flow of the fluid. Turbulent flows are, therefore, unique in their ability to mix momentum and kinetic energy and to erode and transport particles.

PARTICLE ENTRAINMENT

Bagnold described the instant of initial particle motion by a threshold fluid velocity which represents the wind speed at which the most susceptible particle becomes entrained. As a flow passes over a stationary particle, turbulent kinetic energy is imparted to the grain which builds a reservoir of stored potential energy.^[2] Further increases in this energy reservoir cause the grain to oscillate and at the critical point where potential energy exceeds the energy of adherence, the grain lifts, or more accurately is ejected in a near vertical trajectory away from the surface^[2,3] initiating saltation. For a single grain of diameter d , Bagnold showed that the threshold fluid velocity, v_t , required to initiate saltation motion is related to particle diameter by

$$v_t = 5.75A \sqrt{\frac{\rho_p - \rho_f}{\rho_f}} - gd \log \frac{z}{k} \quad (3)$$

where A is isrequired to initi with the value with the valuenitiate saltati, ρ_p is particle density, ρ_f is fluid

density, g is gravity force, z is the height for which threshold velocity is being calculated, and k is the surface roughness height equal to about 1/30 the surface grain diameter.

For the case of a naturally irregular surface, such as a field or a sand dune, fluid threshold is not defined by a single wind speed or particle size but by a continuum of wind speeds over a length of time where grains of various diameter become entrained almost simultaneously.^[4]

Once these grains are ejected into the overriding flow, they attain a high-energy ballistic trajectory that depends on particle size and wind velocity^[1,5,6] (Fig. 2). Heavier and larger particles will travel relatively close to the surface (A) contrasted to lighter and smaller particles that initially are ejected higher into the wind profile (B). At some distant point downstream, these grains (impactors) will impact on the sediment bed and either rebound upward again (C), eject new impactors (D), or lodge in the loose sediment. In either case, it is probable that upon impact sufficient kinetic energy will be transferred to one or several additional grains that are “splashed,” or dislodged a short distance (E) known as reptation,^[5,6] a low-energy process that includes a small number of grains traveling upstream. Reptation includes what Bagnold referred to as creep—grains that are too large to be entrained aerodynamically and move by rolling or sliding along the surface. Impact force is also a primary method leading to the disaggregation of larger particle agglomerates by breaking particle bonds or the particles themselves into smaller pieces, enabling aerodynamic transport.

Saltation, which is defined as movement in a series of short hops, includes particles in the high-energy population (A, B, C, and D). These particles are initially moved by wind speeds exceeding the fluid threshold and subsequently through surface impacts that eject new particles at a point known as the impact threshold. Bagnold suggested that the impact threshold involves the same mechanics included in Eq. 3 except $A=0.08$. In other words, after saltation is initiated, additional grains are placed in motion at the threshold impact velocity that is about 80% of the threshold fluid velocity. This infers that once motion has begun, further motion can be sustained at wind speeds less than those required for initial grain motion.

Fig. 2 Particle transport paths in response to the wind profile (at left). A, B, C, and D are high-energy impacting grains moving in saltation. E are low-energy reptating particles including those moving by creep.

Fig. 3 Vertical and horizontal mass flux profiles for two wind events illustrating the decrease and increase of mass with height and downstream distance, respectively.
Source: Data from Stetler & Saxton.^[10]

The third transport mode, suspension, occurs in grains that are small enough to respond directly to turbulent fluctuations and thus are lofted above the surface saltation layer.

SELF-BALANCING CONCEPT

Energy required to transport particles comes from the extraction of turbulent momentum contained in the flow and a reduction in shearing forces near the surface.^[7,8] Thus, as the flow adjusts to the presence of particles, a self-balancing condition in mass flux develops downstream of the point of initial grain motion.^[9] In other words, the carrying capacity of the wind has been realized. This does not imply additional particles are not eroded, but that as larger grains become deposited behind surface roughness elements, the loss of mass is balanced by erosion of new grains from the surface, primarily by impact and abrasion forces.

The self-balancing concept for maximum horizontal mass flux, $f_{\max}$, has been analyzed by Stout,^[8] reducing to the following formula

$$f_x = f_{\max}(1 - e^{-\frac{x}{b}}) \quad (4)$$

where f_x is horizontal mass flux at downstream distance, x , from a non-eroding boundary and b is the length scale for stability in horizontal mass flux and is applied to height-specific mass flux measurements. In utility, Eq. 4 states that beginning from a non-eroding boundary at $x = 0$, f_x increases with x until $f_{\max}$ is attained. Downstream of this point, horizontal mass flux is relatively unchanged. Typical vertical and horizontal mass flux profiles from two wind events are shown in Fig. 3.^[10] Two components require discussion. First, vertical mass flux profiles, from 0.1 m to 1.5 m height, show mass decreases with height. This is

consistent with the discussion above, i.e., saltating particles having less mass loft higher into the flow. For any single profile, mass is the greatest near the surface and decreases vertically. Second, horizontal mass flux increases downstream until the maximum transport capacity is reached. In the figure, mass continues to increase downstream not yet having attained $f_{\max}$.

CONCLUSION

Complications to the abovementioned processes arrive due to numerous natural and human-induced conditions including soil type, particle size distribution and fraction of erodible particles, climate, and land use. In cultivated fields, surface roughness is a primary consideration complicating the entrainment process as well as the establishment of the saltation layer. Rough surface elements have the effect of reducing wind shear forces, thereby limiting erosion contrasted to a smoother surface that is favorable for a higher erosion rate.^[11] Surface roughness can be either from soil clods, vegetation, or a combination of both.^[12] Additionally, given all the factors discussed above, increases in soil moisture will cause an increase in the wind speed required to initiate grain motion.^[13]

The prediction of wind erosion is, therefore, an inexact science, even with the advent of sophisticated computer models. The numerous and complex relations between all the critical parameters imply a degree of uncertainty, even in the best of calculations.

Wind Erosion: Soil Quality and Productivity

John Leys

Gunnedah, New South Wales, Australia*

Abstract

Wind erosion of agricultural land has negative effects on soil quality and soil productivity. The winnowing of the clay, silt, and organic fractions from the surface soil and its transport off-site during wind erosion result in nutrient decline and a reduction in water-holding capacity of the soil. Sandy soils are more prone to wind erosion and suffer the greatest impact of soil and nutrient loss. The loss of soil productivity through wind erosion impacts the subsequent crop production. The level of decline in crop production depends on the crop, soil, and climatic factors. The use of inorganic fertilizers to replace lost nutrients assists in maintaining crop production but does not fully compensate for eroded particles and nutrients. Minimizing erosion is the best way to maintain soil quality and productivity.

INTRODUCTION

Accelerated erosion on agricultural lands has adverse effects on soil quality and productivity through the removal of soil particles and nutrients. The majority of reviews on this topic have concentrated on the impact of water erosion on soil and crop productivity.^[1,2] However, there are a growing number of researches on the impact of wind erosion on soil quality and productivity, which is the focus of this entry.

Wind erosion reduces soil quality and production using a mechanism different from that of water erosion. Water erosion removes the soil en masse, while wind erosion winnows the finer/lighter particles from the surface, leaving the larger (generally inert) particles behind. As a result, wind erosion removes topsoil^[3] and reduces the soil clay and silt content^[4] and the organic matter.^[5] Wind erosion also has an impact on crop productivity. It sandblasts emerging crops,^[6] reshapes the land surface, thereby making it difficult to traverse with wide agricultural implements, buries or undermines infrastructure such as fences and roads, and buries adjacent land with sand drift. This results in limiting the drifted land's production in the short term.^[7] Off-site impacts will not be discussed here, although wind erosion also has considerable off-site impact—e.g., reduces visibility,^[8] deposits unwanted dust and off-farm associated contaminants, and raises airborne particulate levels,^[9] with particle sizes less than 10 μm (PM_{10}), which can have adverse health effects.^[10]

SOIL QUALITY

Soil quality is generally adversely affected by wind erosion via the removal of soil fines (clay, silt, and organic fractions). Soil texture changes are largely irreversible, unless

topsoil is imported to the site. The quantification of the changes in soil texture, as well as identifying the eroded fractions in the eroded sediments, indicates the magnitude of the decline in soil quality brought about by wind erosion. The descriptions of soil texture changes and the eroded sediments will be presented in the next two subsections.

Soil Texture Changes

The impact of erosion on soils has been measured over many years by using many different methods. Long-term analysis of soils exposed to wind erosion^[11] showed a decline in the fertility and particle size distribution (PSD) of the surface soil. Over a 36-year period, a 6.5% increase in the sand fraction of the top 0–10 cm has been reported for Midwestern United States.^[12] The comparison of the PSD of a soil that had been farmed for 30 years and had suffered periodic erosion with that of an adjacent soil under native vegetation^[13] revealed a loss of fines in the 10–100 μm fraction, as well as an increase in the coarse 350–1000 μm fraction (Fig. 1). Increases in the saltation fraction (>250 μm), and reduction in the 75–210 μm fraction, have been reported for the top 1-cm soil layer over a 15-week period for southeastern Australia.^[3] Further research at the same site using a portable field wind tunnel indicated an increase in the dominant sediment population of PSD of the surface soil layer (approximately 0–500 μm depth) after a 30-minute simulated erosion event. The analysis indicates that for the soil cultivation ridges, the proportion of the 300 μm sediment population increased from 60% in the parent soil to 86% after the simulated erosion. In the cultivation furrows, the 420 μm population increased from 0% to 85%. The analysis of the eroded

Fig. 1 PSD of two adjacent soils. One has been farmed for 30 years and has undergone repeated erosion; the other is under native vegetation. The PSDs show an increase in the coarse fraction (arrow a) and a decrease in the finer fraction (arrow b) in the eroded soil.

sediments indicated that >78% of material being eroded fell within the 180 μm population, compared with 29% in the parent soil. The increase in the coarser fractions of the surface soil and the high proportion of finer fractions in the eroded sediment imply that wind erosion is winnowing the fines.

Eroded Sediments

A large number of studies in North America,^[14] Belgium,^[15] Nigeria,^[16] Australia,^[3] and China^[17] show that the particle size decreases as the height increases, indicating a selective sorting of the eroded particles. When the vertical component of the wind exceeds the fall velocity of the eroded particles, they are removed from the site along with their associated nutrients. Australian results indicate that for a 1-week period of monitoring, 27% of the total eroded sediment is in the suspension fraction and thus is removed from the eroded field.^[3] These studies further highlight the winnowing action of the wind erosion processes and the potential loss of soil and nutrients.

SOIL PRODUCTIVITY

When soil is eroded from a site, there is often a subsequent decrease in rooting depth and available water-holding capacity.^[13] There is also a loss of nutrients and a subsequent decline in soil productivity. So if there is wind erosion, where does the nutrient go and how much impact does it have on crop production?

Soil Nutrient Loss

There is considerable evidence that wind-eroded sediments are enriched with nutrients. The nutrient loss has been measured at the site of dust emission, at various heights above the eroded surface, and at downwind sites of the eroded area, immediately adjacent to drift banks of soil and from deposited dust. It is important to examine the magnitude of this nutrient loss.

The nutrient content and particle size of eroded sediments collected at 0–0.5 m height during wind tunnel tests were similar to source sediments.^[18] However, if the sediments are sieved and the <90 μm fraction of the sediments are analyzed, then there are significant enrichment ratios, where the enrichment ratio is the ratio of the nutrient concentration in the eroded sediment to the nutrient concentration of the source soil. The sieve size of 90 μm was chosen because the modal particle size of sediments collected by using wind vane samplers^[19] from field trials in Australia, where the wind tunnel studies were undertaken, was all less than 90 μm for sediments collected at or greater than 0.5 m.^[3]

The mean enrichment ratio (standard deviation in parentheses) of eroded sediments sampled in a wind tunnel with a 4-m working section, for 25 sites, each replicated 10 times, for a range of farming systems and soil types in the drier agricultural areas of South Australia, was 3.43 (1.89) for total nitrogen (N), 2.53 (1.09) for total phosphorus (P), and 5.00 (2.46) for organic carbon after 1-minute duration of 75 km/hr wind.^[20] Therefore, there is significant winnowing of nutrients and enrichment of eroded sediments, even over short distances, i.e., 4 m.

The mean (standard deviation in parentheses) emission rates of nutrients from the above mentioned 25 sites (in $\text{g}/\text{m}^2/\text{sec}$) were 0.0007 (0.0008) for total N, 0.0002 (0.0002) for total P, and 0.0086 (0.0108) for organic carbon after a 1-minute duration of the 75 km/hr wind.

Analysis of dust collected in passive dust samplers at the source area shows that with increasing height above the ground, nutrient concentration increases, along with a decrease in particle size (Fig. 2).^[13] This indicates that the greater the sorting of the sediments, the greater the nutrient concentration in the eroded sediments.

Enrichment ratios of deposited sediment increase with distance from the erosion source because the sediments become more sorted. Measurement of wind-eroded material deposited near eroding fields has enrichment ratios in the order 1.21 for total N and 1.25 for organic carbon;^[21] therefore, some nutrient is redistributed locally. For one study in southeastern Australia, the enrichment ratios of 7.84 for total N and 2.96 for total P have been reported with the corresponding deposition rates of 0.0034 $\text{g}/\text{m}^2/\text{day}$ for total N and 0.0008 $\text{g}/\text{m}^2/\text{day}$ for total P.^[22]

The previous discussion reveals that a significant enrichment of eroded sediments occurs and that this enrichment

Fig. 2 Relationship between nutrient concentration and height for eroded sediments.

Source: Adapted from Leys & McTainsh.^[13]

increases with distance from source, both vertically and horizontally. The magnitude of this loss is large enough to influence subsequent crop production.

Crop Production Decline

There have been many experiments to test the assumption that soil loss causes crop production decline. The basic method has been to scalp off the surface soil and measure the subsequent changes in crop production. However, this approach is not entirely applicable to wind erosion because of the selective nature of the wind erosion processes, as previously described. The problem is compounded because plant response to erosion is complex.

Wind erosion winnows the finer fractions from the soil surface. When these sediments are analyzed, they do show considerable enrichment in nutrients compared to the soil from which they were derived. But is this nutrient loss significant?

Erosion can impact crop production because there is a reduction in the soil depth,^[23] a direct reduction in the amount of nutrients and water availability,^[13] or a combination of both.

Trial results are inconclusive, with some crops in some years showing no yield effects.^[24] Canadian research shows a linear decrease with increasing wind erosion severity.^[25] For spring wheat, the results demonstrate that for every 1 m across a 200-m field, there was a decline in grain yield of 3.6 kg/ha. When the experiment was repeated for canola the following year, no yield depression was

observed. Similarly, results in the United States revealed yield depression for two consecutive years for grain sorghum and kenaf, but this was not seen in each year for cotton and forage sorghum, owing to the climatic variations between years.^[24] It has also been suggested that above-average rainfall may also compensate for nutrient loss.^[26] This would further mask the effects of nutrient loss on soil production.

Nutrient Restoration

The obvious solution to nutrient loss is to replace it with the next crop. Previous studies demonstrate that additional fertilizers only partially compensate for nutrient loss from erosion.^[27] The effects of fertilizer are highly dependent on soil type, soil depth, the level of erosion, the initial fertilizer level, and the chemistry of the soil (i.e., P can be bound up in soils with high calcium carbonate).

CONCLUSION

Wind erosion of agricultural land has negative erosion effects on soil quality and soil productivity. The winnowing of the clay, silt, and organic fractions from the surface soil, and its transport off-site during wind erosion result in nutrient decline and a reduction in water-holding capacity of the soil. Sandy soils are more prone to wind erosion and suffer the greatest impact of soil and nutrient loss. The loss of soil productivity through wind erosion impacts the subsequent crop production. The level of decline in crop production depends on the crop, soil, and climatic factors. The use of inorganic fertilizers to replace lost nutrients assists in maintaining crop production but does not fully compensate for eroded particles and nutrients. Minimizing erosion is the best way to maintain soil quality and productivity.

Windblown Dust

Dale Gillette

U.S. Environmental Protection Agency (EPA), Research Triangle Park, North Carolina, U.S.A.

Abstract

Windblown dust may be understood in terms of generation, transport, and deposition. By mass, windblown dust is probably the single largest contributor to particles in the earth's atmosphere. The dominant mechanism for dust emission is "sandblasting," wherein sand-sized grains are initially made airborne; these sand grains either blast dust particles into the air from coatings of aggregated fine particles on larger particles, or splash fine particles from a reservoir of loose and fine particles. Size distributions of dust particles are broadly similar, despite differences in parent soil material, wind power, and other environmental factors.

INTRODUCTION

The composition of dust is similar to the composition of its parent material. However, enrichments of certain elements or minerals are explained by the size distribution of parent soil minerals and the activity of soluble material. Dust residence time in the atmosphere is approximately less than 30 days, but windblown dust can be transported over phenomenal distances (e.g., across the Atlantic from the Sahara Desert to the Caribbean and North America).

Windblown dust rarely rises above the troposphere, and wet and dry deposition act to remove it from the atmosphere. Long-term mean deposition rates of windblown dust vary widely approximately $10 \text{ g m}^{-2} \text{ yr}^{-1}$ for undisturbed desert areas in the United States; $10\text{--}100 \text{ g m}^{-2} \text{ yr}^{-1}$ for disturbed land areas and urban locations; and several hundred $\text{g m}^{-2} \text{ yr}^{-1}$ for locations within a few hundred kilometers of strong dust areas such as the Sahara.

EMISSION OF DUST

Although sufficiently strong winds can entrain dust directly, the predominant mechanism for emission of dust particles smaller than $10 \mu\text{m}$ (PM_{10}) is abrasion of larger particles that previously became airborne. There is a minimum threshold friction velocity (u_{*t}) for individual particles to be entrained into the airstream from a smooth surface.^[1] This minimum u_{*t} occurs for a particle diameter of approximately $100 \mu\text{m}$. Dust particles require much larger wind forces to remove them from the surface compared with sand-sized particles with diameters of approximately $100 \mu\text{m}$. Because loose particles of $100 \mu\text{m}$ are often found on soil surfaces, a "sandblasting" mechanism is almost always available for unprotected soils exposed to high winds. Physically, sand

grains localize kinetic energy onto small target areas compared with that of the fluid energy transfer with the surface. Experiments have confirmed that particle-to-particle interaction (sandblasting) on an erodible surface is an important and probably dominating mechanism that produces suspension particle flux.

A model for the particle flux of dust produced by the impacts of saltating particles showed that the vertical mass flux of dust particles (F_a) is proportional to the horizontal sand flux (q_{tot}) integrated over the total depth of the sand layer, multiplied by the mass per particle and divided by a binding energy Ω . The quantity Ω is characteristic of the strengths that hold dust particles in the soil. In other words, the model says that the ratio F_a/q_{tot} is related to the particle size of the saltating grains along with the binding energy of the dust particles.

Simultaneous data^[4] on horizontal fluxes of sand (q_{tot}) and vertical fluxes of PM_{10} (F_a) on agricultural soils in Texas formed a body of experimental work with which to evaluate the above model for F_a/q_{tot} . These results (Fig. 1) show that the ratio F_a/q_{tot} for "sand" textures is highly variable but has a consistency regardless of friction velocity, which is proportional to wind speed. That is, for sandy-soil textures, the sandblasting model for dust emission seems consistent with observations.

Sources of windblown dust are natural and anthropogenic. Natural sources include deserts, such as the Sahara, where there is lack of vegetation and (in some areas) soil crusting, coarse gravel and boulders, and presence of fine and sandy material in the soil. In the United States and other locations, deserts have more protection by vegetation, soil crusting, and coarse elements in the soil so that total dust emissions are smaller per unit area of desert. Highly active wind elements such as dust devils produce intense but highly local emissions when they encounter bare and loose soil.

Fig. 1 Ratio of vertical flux of dust to horizontal flux of sand (per meter) vs. friction velocity (meters per second).

Source: From Gillette, Fryrear, et al.^[4]

Disturbances by man that leave large areas of loose soil exposed to high winds are some of the largest causes of wind-blown dust emissions. Examples of these are agriculture, diversion of rivers, and vehicular travel in arid and semiarid lands.

SIZE DISTRIBUTIONS AND OPTICAL PROPERTIES OF DUST

The distributions of dust mass concentration have been observed to be normal in logarithm of particle size (i.e., lognormal) with two modes. For many different wind speeds above the threshold (lower limit), researchers^[5] have found that there is a constant shape of dust mass size distribution for particles smaller than 10 μm . Scanning electron microscope analysis of typical dust samples shows that many particles are aggregated and that individual particles have differing mineralogies.

An explanation^[6] of the constant shape for dust size distributions is that the kinetic energy of individual saltating grains, along with the kinetic energy required to release suspendable particles, determines the quantities of different sizes of emitted dust. The huge variation in particle bond strengths and particle sizes explains the variability of F_a/q_{tot} as shown in Fig. 1, despite the overall similarity of dust size distributions produced over widely different soil locations and wind strengths.

Optical properties of the dust sampled in the United States may be summarized as a typical complex index of refraction for U.S. soil dust for visible light (488 nm); the real part of the index of refraction = 1.525 and the imaginary part of the index of refraction = 0.005i. For Saharan dust, the index of refraction was $1.55 + 0.008i$. Visibility studies using the formula $M = C/V$, where M is the mass concentration of soil aerosols (g m^{-3}) and V is

horizontal visibility (km), measured the constant C as $0.011 \text{ g m}^{-3} \text{ km}$.

COMPOSITION OF DUST

Mineralogically (chemically), a general model^[7] of dust for particles 1–10 μm consists of (in order of the most abundant): quartz, mica, kaolinite, mixed-layer phyllosilicates, and feldspars. For particles smaller than 1 μm , the order is: mica, kaolinite, quartz, and mixed-layer phyllosilicates. Particles from 10 to 100 μm are usually almost exclusively quartz grains characteristically coated with clay. The finer mode particles (1–10 μm) are similar to clay platelets that stick to the surface of larger quartz particles. Collisions of sand-sized particles with other particles (sandblasting) act to release portions of aggregated particles and break up the crystalline structure of mineral particles. One soil containing more clay than another “sandier” soil had the proportions of the 1–10 μm mode increase with wind speed relative to the 10–100 μm mode.^[8] But the sandier soil did not.

Usually, desert soils contain higher percentages of calcium carbonates than soils receiving greater rainfall. Because surface calcium carbonates are largely contained as fine particles, coatings, and interstitial material, the mechanisms of dust emission increase (enrich) the amount of calcium present in dust compared with that of the soil from which it was derived. Similar enrichments are found for other trace elements, such as the aluminum associated with clay composition. Soluble material, such as sodium chloride, is enriched in some barren desert soils. This concentration takes place through transport by water to low places, where the water is then lost largely through evaporation. Enrichment of salts in dust is also observed, especially at playas (drainage basins). Because windblown dust is rich in calcium carbonates, the percentage of carbonate may range from 5% to 25% by mass in deposited dust. Also, because soluble materials are concentrated at the surface in arid regions, salt content ranges from 0% to 20% by mass in deposited windblown dust.

TRANSPORT OF WINDBLOWN DUST

After being emitted from the surface to the air, windblown dust has the potential for transport. An approximate size limit for dust having the potential for long-range transport was defined as the size at which the fall (sedimentation) velocity is less than or equal to 0.1 times the friction velocity of the wind.^[9] As the smallest friction velocity for the threshold of particle movement is approximately 20 cm s^{-1} , the size limit corresponds to a particle having a sedimentation velocity of 2 cm s^{-1} . For soil-derived particles with densities of approximately 2500 kg m^{-3} , this corresponds roughly to particle diameters between 10 and 20 μm . Particles of this size with potential for long-range transport

could be depleted by deposition within a few minutes following their emission.^[10]

Although most dust is deposited near its point of origin, a small fraction of the dust emitted can be transported great distances. For example, dust has been shown to have transported from the Sahara Desert to Miami, Florida.^[11]

DEPOSITION OF WINDBLOWN DUST

Studies in desert regions that are not considered major global contributors of dust have sampled dust deposition, taking great care to exclude bird contributions and sand particles that are probably of local origin. The results showed that typical values of deposition for southern Nevada and southeastern California are 4.3–15.7 g m⁻² yr⁻¹.^[12] Typical values for south-central New Mexico (northern Chihuahuan desert) are 7.6–28.1 g m⁻² yr⁻¹.^[13] Depositions in urban desert areas of the United States are typically higher (e.g., 48 g m⁻² yr⁻¹);^[14] these values reflect dust contributions from anthropogenic disturbances of the soil followed by wind erosion on the disturbed soil.^[15]

Deposition rates downwind of agricultural areas, such as in western Texas, range from 10.8 to 13.7 g m⁻² yr⁻¹,^[16] whereas in the Great Plains of the United States rates range from 20.2 to 90.8 g m⁻² yr⁻¹.^[17] These higher deposition rates reflect sporadic large depositions from dust storms eroding bare farm fields. Deposition rates near major global atmospheric dust contributors, like the Sahara, are higher than other locations. Deposition in the Negev (Israel) ranges from 120 to 300 g m⁻² yr⁻¹.^[18] Rates at Niger, West Africa range from 115 to 138 g m⁻² yr⁻¹.^[19] However, far downwind from major dust sources, deposition rates of 1.3 g m⁻² yr⁻¹ were reported for dust from Africa reaching Miami, Florida.^[11]

Abstract

Wind can make significant changes in the physical characteristics of rains and hence in soil erosion processes. The rainsplash detachment and transport under wind-driven rainfall would differ from that under windless rain. The rainsplash transport may be a significant process to the extent that it may not be negligible in accurately predicting water erosion, and this process may result in a net transportation in the prevailing wind direction.

INTRODUCTION

Wind-driven rain can be described as raindrops falling through a wind field at an angle different from the vertical under the effects of both gravitational and drag forces. A schematic representation of wind-driven rain incidental to a sloping soil surface is given in [Fig. 1](#).

A study of wind-driven rain erosion is an attempt to investigate the combined effect of wind and rain on soil erosion processes in situations where wind and rain occur at the same time.

EFFECTS OF WIND ON PHYSICAL CHARACTERISTICS OF RAINS

Raindrop Size Distribution

In the assessment of the distribution of small simulated raindrops in a wind tunnel, Erpul, Gabriels, and Janssens^[1] obtained a narrower raindrop distribution and observed a distinct increase in mean drop diameter under wind-driven rain compared with windless rain. Collisions between small drops occurred more frequently as a result of their greater number per unit volume in air, leading to an increase in mean drop size. For large drops, however, this would not occur, as large drops are less stable and the wind caused some of them to break up into smaller drops.^[2,3] Basically, the effect of wind on raindrop size distributions is a potentially important effect that needs to be considered when estimating the rainfall erosivity.

RAINDROP IMPACT ENERGY

Wind-driven raindrops gain some degree of horizontal velocity, which increases their resultant impact velocity. The kinetic energy load of the rainfall may be expected to change as a result of increased velocity and the altered size of the raindrops. The exponential relationship between the horizontal wind velocity and the kinetic energy of raindrops was found in natural rains.^[4] The effect of wind on the horizontal component of small raindrops would be greater, so a greater percentage increase in kinetic energy would be expected for small raindrops than for large raindrops.^[5]

Raindrop Impact Angle

Wind-driven raindrops strike the soil surface with an angle deviated from the vertical because of their horizontal and vertical velocities. This inclination depends on the magnitude of wind velocity. In mid-latitudes, rain mostly falls at considerable inclination from the vertical, and the resultant angles of 40–70° have been found in rains driven by wind velocity of 10 m/s.^[6] Gabriels et al.^[7] reported that the mean angles of rain inclination were 52°, 66°, and 67° for the simulated rains in a wind tunnel driven by 6, 10, and 12 m/s of wind velocities, respectively. For these rains, a median drop size was approximately 1.50 mm. Little is known about the physical impact of raindrops on a soil in situations where this impact is not vertical. It is also not known whether inclined raindrops have stronger erosive effects than vertical ones. The extent and magnitude of the

Fig. 1 Schematic representation of wind-driven rain with an angle from the vertical and incident on sloping soil surface.

rainsplash detachment increased as the angle of deviation increased within the range of 5–30°^[8] whereas, with greater deviations, the impact angle could be so small that raindrops would hardly hit the soil surface. Especially when impact angles were less than 30°, rainsplash detachment rate highly decreased (Table 1).

Raindrop Impact Frequency

The distribution and the intensity of rain on sloping surfaces differ depending on wind direction and velocity. In fact, the angle of rain incidence (π), which is a function of rain inclination (α), slope gradient (θ), and slope aspect, determines the rain intensity in wind-driven rains. As an example, a windward-facing slope can receive two times more rain intensity than a leeward-facing slope, or even exceed it in extreme cases for rain inclinations of

40–70°.^[6] When the rain inclination and the slope gradient increase, the discrepancies in the rain intensity between wind slope and leeward slope become greater (Table 1).

EFFECTS OF WIND ON RAINSPLASH DETACHMENT AND TRANSPORT

Rainsplash Detachment

Similar to the effects on rain characteristics, wind movement and velocities can have a profound effect on some aspects of the soil erosion process. When wind accompanies rain, rainsplash detachment tends to increase owing to the increased energy of raindrops. Pedersen and Hasholt^[4] obtained a better correlation between the rainsplash detachment and erosivity indexes, when wind velocity was taken

Table 1 The effect of wind on rain energy, rain intensity, and rainsplash detachment and transport of a silt loam soil.

Note: u, horizontal wind velocity; KE, kinetic energy [the exponential relationship found between KE and u is $E(u)=1.9723e^{0.1796u}$ (the relationship between columns 1 and 2)]; α , rain inclination from vertical; θ , slope gradient; π , angle of rain incidence calculated using rain inclination, slope gradient, and slope aspect by cosine law: $\cos(\pi)=\cos(\alpha-\theta)=\cos\alpha\cos\theta+\sin\alpha\sin\theta$ for windward slopes and $\cos(\pi)=\cos(\alpha+\theta)=\cos\alpha\cos\theta-\sin\alpha\sin\theta$ for leeward slopes; I, rain intensity; D, rainsplash detachment rate; X_c , mean rainsplash distance calculated by the center of gravity of mass distribution curves; and q_s , rainsplash transport estimated by $q_s=DX_c$.

into account in the kinetic energy calculation. However, the wind not only increased the raindrop impact energy, but also altered the angle of rain incidence, resulting in the variations in the raindrop impact frequency and the raindrop impact angle. In other words, raindrop impact energy, impact frequency, and impact angle determine the magnitude of rainsplash detachment under wind-driven rainfall. The influence of each factor on the process is not exclusive and not clearly distinguished, because all are closely related, and each factor is a function of the wind speed. The highest rainsplash rate occurred with the highest impact frequency and the highest impact angle at a given raindrop impact energy under wind-driven rains (Table 1).

Rainsplash Transport

Wind, as well as slope and overland flow, is another possible factor capable of transporting detached particles by raindrop impact. It is possible to find similarities between the movement and trajectory of sand saltation by wind and the movement and trajectory of soil particles by rainsplash under wind-driven rainfall. In saltation, the hitting sand grains, once ejected, initiate the motion of uplift,^[9] whereas hitting raindrops on the soil surface with an angle initiate a jumping movement of soil particles in wind-driven rainfall.^[10] A threshold is given by impacting raindrops, and wind does not account for the upward movement except that it changes the energy, frequency, and angle of raindrop impact. Once soil particles are entrained in the splash droplets that have risen into the air by raindrop impact, wind velocity gradient will transport these particles. It is found that, together with wind velocity gradient, the impact angle is also playing a significant role in determining the extent of the process. At the same wind speed, longer mean rainsplash distances (X_c) were observed when the impact angle became greater (Table 1). There was a very discernible decrease in X_c in leeward-facing slopes, which was mostly associated with the impact angles of less than 30° . These

results showed that the raindrop impact angle might determine the soil particle ejection angle.

As mentioned above, the amount of soil particles to be transported by the wind will depend on the raindrop impact energy, impact frequency, and impact angle. Subsequently, the soil particle ejection angle and the wind velocity gradient will determine the extent of the process (Fig. 2).

CONCLUSION

Wind could make significant changes in the physical characteristics of rains and hence in soil erosion processes. The rainsplash detachment and transport under wind-driven rainfall would differ from that under windless rain. The rainsplash transport could be a significant process to the extent that it may not be negligible in accurately predicting water erosion, and this process could result in a net transportation in the prevailing wind direction.

Abstract

The international soil classification system, World Reference Base (WRB) for Soil Resources, is edited by a Working Group of the International Union of Soil Sciences (IUSS) and published by the Food and Agriculture Organization of the United Nations (FAO). The third edition was released in 2014. The WRB has two hierarchical levels. The first level comprises 32 Reference Soil Groups (RSGs), which are identified using a key. Many RSGs represent specific soil-forming processes or major soil regions. At the second level, the soil names are constructed by adding qualifiers to the name of the RSG. In total, 184 qualifiers are defined. Some can be combined with many RSGs, others with only a few. For every RSG, a list of the available qualifiers is provided. They are subdivided into principal (ranked and given in an order of importance) and supplementary qualifiers (not ranked, but in alphabetical order). In the WRB, diagnostic horizons, properties, and materials are defined. Diagnostic horizons and properties reflect common results of soil-forming processes or indicate specific conditions of soil formation. In addition, diagnostic horizons require a certain thickness. Diagnostic materials significantly influence pedogenetic processes or are indicative of them. The definitions of many RSGs and qualifiers refer to the presence or absence of diagnostics. In addition, many definitions refer to individual characteristics such as clay content. To name a soil, the RSG has to be provided with all applying qualifiers. For map legends, the number of qualifiers depends on scale and purpose of the map.

INTRODUCTION

The third edition of the international soil classification system, World Reference Base (WRB) for Soil Resources, was released in June 2014. In 2015, an update of the third edition of the WRB was published with some minor corrections and amendments.^[1] The third edition is based on the second (2006) and the first (1998) editions. The WRB builds on the Legends (1974, 1988) of the Soil Map of the World (FAO–UNESCO 1971–1981). The body responsible for revising and editing the WRB is a Working Group of the International Union of Soil Sciences (IUSS). In 1998, the IUSS Council endorsed the WRB as its officially recommended terminology to name and classify soils.

In WRB, soils are classified at two categorical levels. The first level has 32 Reference Soil Groups (RSGs), which are identified using a key. In the second level, the soil names are constructed by adding a set of qualifiers to the name of the RSG.

THE FIRST LEVEL

RSGs are groups of soils sharing morphologic, physical, and chemical characteristics, as they have undergone similar formation processes or have been formed from particular parent material or represent major soil regions. [Table 1](#)

presents the 32 RSGs in the sequence of the key, together with a brief and simplified description.

THE SECOND LEVEL

For the lower level, 184 qualifiers have been defined. Some can be combined with many RSGs, others with only a few or even with just one. The qualifiers available for use with a particular RSG are listed in the key, along with the RSG. They are divided into principal and supplementary qualifiers. Principal qualifiers are regarded as being the most significant for a further characterization of soils of the particular RSG. They are ranked and given in an order of importance. Supplementary qualifiers give some further details about the soil. They are not ranked and must be used in alphabetical order. The Cambisols have the longest list with 67 possible qualifiers, and the Nitisols have the shortest list with 34 possible qualifiers. Many qualifiers are mutually exclusive, and, in practice, most classified soils have fewer than 10 qualifiers.

THE DIAGNOSTICS

In the WRB, diagnostic horizons, properties, and materials are defined. Diagnostic horizons and properties are

Table 1 Simplified guide to the RSGs (IUSS Working Group WRB 2014, Update 2015).

Brief description/principal characteristics	RSG
1. Soils with thick organic layers	Histosols
2. Soils with strong human influence	
With long and intensive agricultural use	Anthrosols
Containing significant amounts of artefacts	Technosols
3. Soils with limitations to root growth	
Permafrost affected	Cryosols
Thin or with many coarse fragments	Leptosols
With a high content of exchangeable sodium	Solonetz
Alternating wet–dry conditions, shrink–swell clays	Vertisols
High concentration of soluble salts	Solonchaks
4. Soils distinguished by Fe/Al chemistry	
Groundwater affected, underwater and in tidal areas	Gleysols
Allophanes or Al–humus complexes	Andosols
Subsoil accumulation of humus and/or oxides	Podzols
Accumulation and redistribution of Fe	Plinthosols
Low-activity clay, phosphorus fixation, many Fe oxides, strongly structured	Nitisols
Dominance of kaolinite and oxides	Ferralsols
Stagnating water, abrupt textural difference	Planosols
Stagnating water, structural difference, and/or moderate textural difference	Stagnosols
5. Pronounced accumulation of organic matter in the mineral topsoil	
Very dark topsoil, secondary carbonates	Chernozems
Dark topsoil, secondary carbonates	Kastanozems
Dark topsoil, no secondary carbonates (unless very deep), high base status	Phaeozems
Dark topsoil, low base status	Umbrisols
6. Accumulation of moderately soluble salts or non-saline substances	
Accumulation of, and cementation by, secondary silica	Durisols
Accumulation of secondary gypsum	Gypsisols
Accumulation of secondary carbonates	Calcisols
7. Soils with a clay-enriched subsoil	
Interfingering of coarser-textured, lighter coloured material into a finer-textured, stronger coloured layer	Retisols
Low-activity clays, low base status	Acrisols
Low-activity clays, high base status	Lixisols
High-activity clays, low base status	Alisols
High-activity clays, high base status	Luvissols

(Continued)

Table 1 Simplified guide to the RSGs (IUSS Working Group WRB 2014, Update 2015). (Continued)

Brief description/principal characteristics	RSG
8. Soils with little or no profile differentiation	
Moderately developed	Cambisols
Sandy	Arenosols
Stratified fluvial, marine, and lacustrine sediments	Fluvisols
No significant profile development	Regosols

Note: Al = aluminum; Fe = iron.

characterized by a combination of attributes that reflect widespread common results of the processes of soil formation or indicate specific conditions of soil formation. Their features can be observed or measured, either in the field or in the laboratory, and require a minimum or maximum expression to qualify as diagnostic. In addition, diagnostic horizons require a certain thickness, thus forming a recognizable layer in the soil. Diagnostic materials are materials that significantly influence pedogenetic processes or are indicative of them. Their features may stem from the parent material or may be the result of pedogenetic processes. The definitions of many RSGs and qualifiers refer to the presence or absence of diagnostics at a certain depth. In addition, many definitions refer to individual features such as the base saturation or clay content.

NAMING A SOIL (A PROFILE)

The first step is detecting diagnostic horizons, properties, and materials. In the second step, the RSG is identified using the key. In the third step, all applying principal and supplementary qualifiers are allocated. The principal qualifiers are added before the name of the RSG without brackets and commas. The sequence is from right to left, i.e., the uppermost qualifier in the list is placed closest to the name of the RSG. The supplementary qualifiers are added in brackets after the name of the RSG and are separated from each other by commas. The sequence is from left to right, i.e., the first qualifier according to the alphabet is placed closest to the name of the RSG.

Constructing the second level by adding qualifiers to the RSG rather than by using a dichotomic identification key has several advantages:

- For every soil, the RSG has the appropriate number of associated qualifiers.
- Most of the soil's properties are incorporated into an informative soil name.

- The system is robust. When some data are not available, the classification does not lead to a fundamental error in the soil name. If a qualifier is erroneously added or omitted due to incomplete data, the rest of the soil name remains correct.

CREATING MAP LEGENDS

Whereas for naming a soil, all applying qualifiers must form part of the soil name, for elaborating map legends, the number of qualifiers will depend on the scale and purpose of the map. The WRB recognizes four scale levels:

- for very small map scales, only the RSG is used.
- for next larger map scales, the RSG plus the first applicable principal qualifier is used.
- for next larger map scales, the RSG plus the first two applicable principal qualifiers are used.
- for next larger map scales, the RSG plus the first three applicable principal qualifiers are used.

If fewer qualifiers are applicable than described above, the lesser number is used. The principal qualifiers are placed before the name of the RSG according to the rules for naming a soil. Other qualifiers may be added optionally depending on the purpose of the map or according to national traditions, and irrespectively of the map scale. These additional qualifiers may be principal qualifiers from further down the list, or supplementary qualifiers, and must be used according to the above-mentioned rules for supplementary qualifiers.

For most maps, it is desirable that a map unit does not show a single soil but an association of soils. The WRB distinguishes:

- dominant soils represent $\geq 50\%$ of the soil cover.
- codominant soils represent $\geq 25\%$ and $< 50\%$ of the soil cover.
- associated soils represent $\geq 5\%$ and $< 25\%$ of the soil cover.

For codominant or associated soils, fewer numbers of qualifiers than indicated above (or even no qualifier) may be appropriate.

SUBQUALIFIERS

Qualifiers may be combined with specifiers (e.g., Epi-, Proto-) to form subqualifiers (e.g., Epiarenic, Protocalcic). Depending on the specifier, the subqualifier fulfills all the criteria of the respective qualifier, or it deviates in a defined way from its set of criteria. The use of specifiers does not change the position of the qualifier in the soil name. Only if principal qualifiers are combined with the specifiers, Bathy-(greater depth), Thapto-(buried), or Proto-(weaker

expressed), the created subqualifier shifts to the supplementary qualifiers. The use of subqualifiers (instead of qualifiers) that deviate from the set of criteria of the respective qualifier is compulsory. The use of subqualifiers (instead of qualifiers) that fulfill all the criteria of the respective qualifier is optional. They are recommended especially for soil-naming soils. Their use is not recommended for principal qualifiers in map units or wherever generalization is important.

Qualifiers that have depth requirements can be combined with the specifiers, Epi-, Endo-, Amphi-, Ano-, Kato-, Panto-, and Bathy- to create subqualifiers (e.g., Epicalcic, Endocalcic) further expressing the depth of occurrence. If a diagnostic horizon or a layer with a diagnostic property belongs to a buried soil that does not meet the requirements of the related RSG (see “Buried Soils”), the Thapto- specifier can be used. For soils having a consolidated layer at shallow depths, subqualifiers with the specifier Supra- can be used to describe the soil material above, if the thickness or depth requirements of a qualifier or of its respective diagnostics are not fulfilled, but all other criteria are fulfilled throughout in the soil material above. Besides these subqualifiers constructed individually, the WRB also provides subqualifiers with a given definition (e.g., Protosalic, Neocambic).

BURIED SOILS

A buried soil is a soil covered by younger deposits. Where a soil is buried, the following rules apply:

1. The overlying material and the buried soil are classified as one soil if both together qualify as a Histosol, Anthrosol, Technosol, Cryosol, Leptosol, Vertisol, Gleysol, Andosol, Planosol, Stagnosol, Arenosol, Fluvisol, or Regosol.
2. Otherwise, the overlying material is classified with preference if it is ≥ 50 cm thick or if the overlying material, if it stood alone, satisfies the requirements of a Folic Regosol or of a RSG other than a Regosol. For depth requirements in the overlying material, the lower limit of the overlying material is regarded as if it were the upper limit of continuous rock.
3. In all other cases, the buried soil is classified with preference. For depth requirements in the buried soil, the upper limit of the buried soil is regarded as its soil surface.
4. If the overlying soil is classified with preference, the name of the buried soil is placed after the name of the overlying soil adding the word “over” in between, e.g., Skeletic Umbrisol (Siltic) over Albic Podzol (Arenic).
5. If the buried soil is classified with preference, the overlying material is indicated with the Novic qualifier.

EXAMPLES

A soil named *Hypereutric Albic Endogleyic Mollic Stagnosol* (*Hyperhumic*, *Inclitic*, *Pantoloamic*) belongs to the RSG of the Stagnosols, which implies that it has a topsoil with perched water, reducing conditions and a typical distribution pattern of iron oxides. Following their ranking order, the principal qualifiers provide more information on the nature of the soil: *Mollic* indicates the presence of a thick, dark, structured mineral topsoil horizon with a high base saturation; *Endogleyic* indicates that the subsoil is influenced by groundwater and shows the related distribution pattern of iron oxides; *Albic* indicates the occurrence of whitish soil material relatively depleted of iron oxides; *Hypereutric* reflects a very high base saturation throughout a depth from 20 to 100 cm. The supplementary qualifiers give additional information—a high average content of organic matter up to a depth of 50 cm (*Hyperhumic*), the occurrences of subsurface water flow (*Inclitic*), and a soil texture that is loamy throughout (*Pantoloamic*).

If we use the same example for creating map units, depending on the scale we have:

- first map scale level: Stagnosol
- second map scale level: Mollic Stagnosol
- third map scale level: Gleyic Mollic Stagnosol
- fourth map scale level: Albic Gleyic Mollic Stagnosol.

(The specifiers have not been used to help for a better aggregation of the soils of a map unit.)

If we want to add additional qualifiers, we may have, for example, the following map units:

- Stagnosol (Gleyic)
- Mollic Stagnosol (Gleyic)
- Gleyic Mollic Stagnosol (Hypereutric, Pantoloamic)
- Albic Gleyic Mollic Stagnosol (Hypereutric, Pantoloamic).

THE MAJOR CHANGES IN THE WRB 2014

Having qualifier sequences and rules for qualifier usage that are suitable for both naming soils and creating map legends is one of the advantages of the third edition compared to the second. Furthermore, the new edition integrates better the needs for classifying soils in landscapes that had been neglected before, e.g., very continental permafrost regions. The WRB as international soil classification system should be able to express characteristics regarded as important in national systems. Some amendments have been made to allow for the better representation of soil units in the WRB, for example, from the Australian and the Brazilian systems. Great efforts were undertaken to write the definitions in a more logical and a more didactical way. Precise rules have been introduced for the use of specifiers to define subqualifiers.

ACKNOWLEDGMENTS

The editors of the third edition of the WRB are: Peter Schad (Germany), Cornie van Huyssteen (South Africa), and Erika Micheli (Hungary). Members of the WRB Board are: Lúcia Anjos (Brazil), Carlos Cruz Gaistardo (Mexico), Seppe Deckers (Belgium), Stefaan Dondeyne (Belgium), Einar Eberhardt (Germany), Maria Gerasimova (Russia), Ben Harms (Australia), Arwyn Jones (European Commission), Pavel Krasilnikov (Russia), Thomas Reinsch (the United States), Ronald Vargas (FAO), and Ganlin Zhang (China). Numerous other soil scientists contributed to the third edition of the WRB.
